Chapter 3: Overview of Temperature and Winds

Chapter lead authors Craig Long National Oceanic and Atmospheric Administration USA (retired) Masatomo Fujiwara Faculty of Environmental Earth Science, Hokkaido University Japan **Co-authors** Sean Davis Chemical Sciences Laboratory, National Oceanic and Atmospheric Administration USA **Daniel Mitchell** University of Bristol UK **Corwin Wright** University of Bath UK

Abstract. Two of the most basic parameters generated from a reanalysis are temperature and winds. Temperatures in the reanalyses are derived from conventional (surface and balloon), aircraft, and satellite observations. Winds are observed by conventional systems, cloud tracked, and derived from height fields, which are in turn derived from the vertical temperature structure. In this chapter we evaluate as part of the SPARC Reanalysis Intercomparison Project (S-RIP) the temperature and wind structure of all the recent and past reanalyses. This evaluation is mainly among the reanalyses themselves, but comparisons against independent observations, such as HIRDLS, MLS, COSMIC, ozonesonde, and rocketsonde temperatures are also presented. This evaluation uses monthly mean and 2.5° zonal mean data sets and spans the satellite era from 1979-2014. There is very good agreement in temperature seasonally and latitudinally among the more recent reanalyses (CFSR/CFSv2, MERRA, ERA-Interim, JRA-55, and MERRA-2) between the surface and 10hPa. At lower pressures there is increased variance among these reanalyses that changes with season and latitude. This variance also changes during the time span of these reanalyses with greater variance during the TOVS period (1979-1998) and less variance afterward in the ATOVS period (1999 – 2014). There is a distinct change in the temperature structure in the middle and upper stratosphere during this transition from TOVS to ATOVS systems. Consult Chapter 2 Section 2.4.3.2 (Observational Data/Satellite Data) for more information about the TOVS and ATOVS suite of instruments and usage by the various reanalyses. Zonal winds for the entire period have lower variance among the reanalyses than the temperatures and this lower variance extends to lower pressures than the temperatures. The temperatures and winds throughout the stratosphere in the older reanayses (NCEP-NCAR R1, NCEP-DOE R2, ERA-40, and JRA-25) show significant differences from a Reanalysis Ensemble Mean for the same time periods than in the more recent reanalyses, both during the TOVS and ATOVS periods. The transition of temperatures from the TOVS to ATOVS periods continues to be an issue even for the more recent reanalyses. All reanalyses to date have issues analysing the quasi-biennial oscillation (QBO) winds. Comparisons with Singapore QBO winds show disagreement in the amplitude of the westerly and easterly anomalies. The disagreement with Singapore winds improves with the transition from TOVS to ATOVS observations. Aura HIRDLS and Aura MLS temperatures have similar bias characteristics when compared with a reanalysis ensemble mean (MERRA, ERA-Interim, and JRA-55). There is good agreement among the NOAA TLS, SSU1, and SSU2 Climate Data Records and layer mean temperatures from the more recent reanalyses. Caution is advised when using reanalysis temperatures for trend detection and anomalies from a long climatology period as the quality and character of reanalyses have changed over time.

Long et al. (2017) have published a shortened version of this chapter.

Reanalyses are used in many ways, including as initial conditions for historical model runs, developing climatologies, comparison with experimental models, and the examination of atmospheric features or conditions over long periods of time. This chapter mainly evaluates eight reanalysis data sets: NCEP-NCAR Reanalysis 1 (Kistler et al., 2001; referred to hereafter as "R1"; Kalnay et al., 1996), ERA-40 (Uppala et al., 2005), JRA-25 (Onogi et al., 2007), NCEP/CFSR (Saha et al., 2010), ERA-Interim (Dee et al., 2011; referred to hereafter as ERA-I), MERRA (Rienecker et al., 2011), JRA-55 (Kobayashi et al., 2015), and MERRA-2 (Gelaro et al., 2017; GMAO, 2015), with some notes on NCEP-DOE Reanalysis 2 (Kanamitsu et al., 2002) (referred to hereafter as R2) and 20CR (Compo et al., 2011). See Chapter 2 for more information about these reanalyses. The ERA-15 (Gibson et al., 1997) is not included in this intercomparison due to its short period and subsequent replacement by ERA-40. When a reanalysis product is chosen for use in a study or comparison, the choice is made based upon several factors such as newness of the reanalysis systems, span of time evaluated, horizontal and vertical resolution, top layer, and observational data assimilated. In this chapter, we present an intercomparison of these 10 reanalyses focusing mainly upon their temperature and zonal wind fields. The five more recent reanalyses (CFSR/CFSv2, MERRA, ERA-I, JRA-55, and MERRA-2) are the primary focus and we concentrate on how these reanalyses intercompare in the upper troposphere and entire stratosphere.

Intercomparisons of middle atmosphere winds and temperatures using reanalyses have been performed since the very first reanalyses were generated in the late 1990s. Pawson and Fiorino (1998a, b; 1999) were the first to evaluate reanalyses winds and temperatures by comparing R1 and ERA-15 analysis of the tropics before and after satellite data were used in the reanalyses. Randel et al. (2004) intercompared wind and temperature climatologies from R1, ERA-15, and ERA-40 along with meteorological centre analyses. R1 and the ERA-40 have been used by thousands of researchers for tropospheric studies. Notable middle atmosphere studies evaluating R1 and ERA-40 winds and temperatures include the following. Manney et al. (2005) used these two reanalyses along with other analyses to evaluate their ability to capture the unique 2002 Antarctic winter, while Charlton and Polvani (2007) intercompared the two for detecting Northern Hemispheric sudden stratospheric warmings (SSWs). Martineau and Son (2010) used temperature and wind fields from R1, R2, JRA-25, ERA-I, and MERRA to compare their depiction of stratospheric vortex weakening and intensification events against GPSRO temperature data. Simmons et al. (2014) intercompared the ERA-I, MERRA, and JRA-55 stratospheric temperature analyses over the 1979-2012 period showing where and when they agreed and disagreed and the reasons why they did so. They also pointed out the difficulties of the transition from the TOVS to ATOVS observations, most notably in the upper stratosphere and lower mesosphere. Lawrence et al. (2015)

used polar processing diagnostics to compare the ERA-I and MERRA. They noted good agreement in the diagnostics after 2002, but cautioned that the choice of one over the other could influence the results of polar processing studies. Miyazaki et al. (2016) intercompared six reanalyses (R1, ERA-40, JRA-25, CFSR/CFSv2, ERA-I, JRA-55) to study the mean meridional circulation in the stratosphere and eddy mixing and their implications upon the strength of the Brewer-Dobson circulation. Fujiwara et al. (2015) used nine reanalyses (JRA-55, MERRA, ERA-I, CFSR/CFSv2, JRA-25, ERA-40, R1, R2, and 20CR) to examine their stratospheric temperature response to the eruptions of Mount Agung (1963), El Chichón (1982), and Mount Pinatubo (1991). Mitchell et al. (2015) performed a multiple linear regression analysis on the same nine reanalyses to test the robustness of their variability. Martineau et al. (2016) intercompare eight reanalyses (ERA-40, ERA-I, R1, R2, CFSR/CFSv2, JRA-25, JRA-55, and MERRA) for dynamical consistency of wintertime stratospheric polar vortex variability. Kawatani et al. (2016) compare the representation of the monthly mean zonal wind in the equatorial stratosphere with a focus on the quasi-biennial oscillation (QBO; Baldwin et al., 2001) among nine reanalyses (R1, R2, CFSR/CFSv2, ERA-40, ERA-I, JRA-25, JRA-55, MERRA, and MERRA-2).

The report by the SPARC Reference Climatology Group (SPARC, 2002) and the subsequent journal article by Randel et al. (2004) were in response to the need to compare and evaluate the then-existing middle atmosphere climatologies that were housed and made readily available to the research community at the SPARC Data Centre. Both reports provide an intercomparison of eight middle atmosphere climatologies: UK Met Office data assimilation, NOAA Climate Prediction Center objective analysis, UK Met Office objective analysis using TOVS data, the Free University of Berlin Northern Hemisphere subjective analysis, CIRA86 (COSPAR International Reference Atmosphere, 1986), R1, ERA-15, and ERA-40. This intercomparison was mostly based upon analyses rather than reanalyses, as only the R1, ERA-15, and ERA-40 reanalyses were available at that time. Notable differences were found among analyses for temperatures near the tropical tropopause and polar lower stratosphere and zonal winds throughout the tropics. Comparisons of historical reference atmosphere and rocketsonde temperature observations with the more recent global analyses showed the influence of decadal-scale cooling of the stratosphere. Detailed comparisons of the tropical semi-annual oscillation (SAO) and QBO showed large differences in amplitude among analyses; the more recent data assimilation schemes showed better agreement with equatorial radiosonde, rocket, and satellite data (e.g. Baldwin and Gray, 2005).

This chapter is an extended version of the paper by *Long et al.* (2017). In this chapter we show the results from the eight "full-input" (*Chapter 2*) reanalyses, which are systems that assimilate surface and upper-air conventional and satellite data (*i.e.* MERRA-2, MERRA, ERA-I, JRA-55, CFSR/CFSv2, JRA-25, ERA-40, *R1*), though we will show one figure for 20CR, which is one of the "surface-input" reanalyses. We will concentrate only on the satellite era period of 1979 to 2014.

	Model Version		Horizontal Resolution	Model Levels	Model Top Level	RTM
R1/R2	NCEP MRF	(1995/98)	T62: 1.875°	28 (σ)	3 hPa	Temperature retrievals
CFSR CFSv2	NCEP CFS	(2007) (2011)	T382: 0.3125° T574: 0.2045°	64 (hybrid σ-p)	~0.266 hPa	CRTM
ERA-40	IFS Cycle 23r4	(2001)	TL159: ~ 125 km	60 (hybrid σ-p)	0.1 hPa	RTTOVS-5
ERA-I	IFSCycle 31r2	(2007)	TL255: ~ 79 km	60 (hybrid σ-p)	0.1 hPa	RTTOVS-7
ERA5	IFSCycle 41r2	(2016)	TL639: ~ 31 km	137 (hybrid σ-p)	0.01 hPa	RTTOVS-11
JRA-25	JMA GSM	(2004)	T106: 1.125°	40 (hybrid σ-p)	0.4 hPa	RTTOVS-6 TOVS period RTTOVS-7 ATOVS period
JRA-55	JMA GSM	(2008)	TL 319: ~ 55 km	60 (hybrid σ-p)	0.1 hPa	RTTOVS-9
MERRA	GEOS 5.0.2	(2009)	0.5° lat x 0.667° lon	72 (hybrid σ-p)	0.01 hPa	GLATOVS for SSU; CRTM for others
MERRA-2	GEOS 5.12.4	(2015)	C180: ~ 50 km	72 (hybrid σ-p)	0.01 hPa	CRTM

Table 3.1: Information about NCEP, JMA, ECMWF, and GMAO earlier and later reanalyses pertinent to the stratosphere. Information includes the model version, horizontal resolution, number of model levels, model top pressure, and radiative transfer model (RTM) used for assimilating satellite radiances. See Chapter 2 for more details.

ERA5 results are shown only in Figure 3.1. Several of the reanalyses do not cover the entire span of the later period (e.g. ERA-40 ends in August 2002, 20CR ends in December 2012 (for its version 2), and JRA-25 ends in January 2014). The R2 is an updated version of the R1. Almost all of the changes and enhancements incorporated into the R2 were surface or boundary layer oriented. The only possible change to the stratosphere would be due to a change to a newer ozone climatology (Fujiwara et al., 2017). As a result, preliminary comparisons of R1 and R2 show very minor differences in temperatures and winds above the boundary layer. Therefore, we will not show R2 comparisons, but one can expect all R2 qualities to be nearly exactly the same as R1. All of the reanalyses except for the CFSR/CFSv2 used the same forecast model and assimilation scheme throughout their time span. In 2010 the CFSR/CFSv2 had an undocumented update to its GSI assimilation scheme. Another change to the CFSR/CFSv2 occurred in 2011 with the implementation of the version 2 Climate Forecast System (CFSv2; Saha et al., 2014), in which the resolution, forecast model, and assimilation scheme were all upgraded. Chapter 2 and Fujiwara et al. (2017) distinguish this latter analysis as CFSv2 or CDAS-T574.

The rest of this chapter will be organized as follows: Section 3.2 presents a summary of changes and improvements from each reanalysis centre's earlier to later versions. Section 3.3 presents and discusses temperature variability with time of the reanalyses. Section 3.4 presents the methodology used to compare the various reanalyses, the creation of a reanalysis ensemble mean (REM), and the ensemble mean attributes and variability with time. Section 3.5 presents the differences in the temperatures and winds in individual reanalyses from the REM. Section 3.6 examines the seasonal temperature amplitude of the reanalyses in the polar latitudes. Section 3.7 discusses the results of comparisons with satellite observations that are not assimilated in the reanalyses by showing specific data analyses. Section 3.8 shows comparisons against other types of non-satellite observations. Section 3.9 discusses the effects of volcanic eruptions on reanalysis temperatures and winds. Section 3.10 provides summaries and main conclusions.

We characterize the stratosphere into altitude ranges using the following generalizations: "upper" for 1 hPa to 5 hPa, "middle" for 7 hPa to 30 hPa, and "lower" for 50 hPa to 100 hPa.

3.2 Improvements from older reanalyses to newer versions

Chapter 2 of this report and Fujiwara et al. (2017) provide many details of each reanalysis, such as model characteristics, physical parameterizations used, observations assimilated, execution stream characteristics, and assimilation strategies. The most recent reanalyses are later generations of earlier versions (MERRA and MERRA-2, ERA40 and ERA-Interim, JRA-55 and JRA-25, CFSR/CFSv2, and R1 and R2). Using information contained in Chapter 2, we will highlight what we consider the major improvements and changes from the earlier version to the more recent version. Pertinent to the stratosphere, we present in Table 3.1 a summary of the earlier and later reanalysis models used, model resolution, top pressure level, and radiative transfer model (RTM) used for assimilating satellite radiances. Several reanalyses improved their model horizontal and vertical resolution between versions. All of the later versions used a more recent version of the RTM. Explanations for the various labelling of horizontal resolution can be found in Chapter 2.

3.3 Reanalysis global mean temperature anomaly variability

The 1979 - 2014 period includes the assimilation of satellite observations in addition to the assimilation of conventional (surface, aircraft, and balloon) observations (see *Chapter 2* for details). During this period, there are multiple transitions, additions, and removals of satellites and instruments observing the atmosphere. The calibration and quality control of the observations from these satellite instruments in many instances have improved over time from the earlier reanalysis systems to the more current reanalysis systems. The radiative transfer models used in the forecast models have also improved over time. Reanalysis centres devote major efforts to minimizing the transition from one satellite or observing system to the next (*e.g.* TOVS to ATOVS in 1998; see *Chapter 2*). However, the forecast models used by the reanalysis centres have their own biases throughout the atmosphere. If and how well the bias correction is performed will also dictate how the reanalysis uses these observations. Additionally, most reanalyses are not run as one stream, but rather it is more efficient timewise and computationally for the reanalysis to be broken up into multiple streams with overlap periods of at least 1 or more years (see *Section 2.5* of *Chapter 2*). These overlap periods are intended to allow the new stream to spin up sufficiently to ensure minimal discontinuity when the older stream ends. Because of these factors, it will be shown that the more recent reanalyses have fewer discontinuities at different times throughout this data record than older reanalyses.

Figure 3.1: Pressure versus time plots of the global mean temperature anomalies (K) of reanalyses. The anomalies are from the monthly climatology of each reanalysis. The reanalyses shown are (a) MERRA-2, (b) MERRA, (c) JRA-55, (d) JRA-25, (e) ERA-Interim, (f) ERA-40, (g) CFSR/CFSv2, (h) R1, (i) 20CR, and (j) ERA5. Note that R1 and 20CR do not provide analyses above 10 hPa; "v" and "e" denote the occurrence of volcanos and El Niños. Updated from Long et al. (2017).

To illustrate how well the various reanalyses were able to transition between satellites and other data sources, Figure 3.1 presents time series for each reanalysis of the global mean temperature anomalies from their own long-term (1979-2014) monthly means. In all of the time series plots, several climatic features are evident: the tropospheric warming during the 1998 and 2010 El Niño events (located on the time axis with an "e") and the lower and middle stratospheric warming associated with the El Chichón (1982) and Mount Pinatubo (1991) volcanic eruptions (located on the time axis with a "v"). However, the older reanalyses (ERA-40 and JRA-25) show several distinct discontinuities in the stratosphere. The ERA-40, which was the first reanalysis to assimilate SSU radiances, shows discontinuities during several changes in the NOAA polar satellites with the SSU instrument in the early 1980s. The ERA-40 assimilated both SSU and AMSU-A radiances from the end of 1998 through 2002 (Uppala et al., 2005). The JRA-25 shows smaller discontinuities in the 1980s but has an abrupt change in 1998 coincident with the immediate transition from TOVS (SSU, MSU) to the ATOVS (AMSU) observing systems. The bias correction schemes for the TOVS and ATOVS radiances were also different. Consult Chapter 2 Section 2.4.2 (Quality Control Procedures) to learn more about the various reanalyses' bias correction practices. The combination of both resulted in large discontinuity in the stratosphere (Onogi et al., 2007). Of the five more recent reanalyses, the CFSR/CFSv2 shows multiple discontinuities in the upper and middle stratosphere. This is because the CFSR is made up of six streams (end years: 1986, 1989, 1994, 1999, 2005, 2009) and also because it corrects the biases in the SSU channel 3 observations with a forecast model that has a noted warm bias in the upper stratosphere. After 1998 the CFSR/CFSv2 only used the AMSU-A radiances (it did not assimilate channel 14) and just monitored the SSU channels (Saha et al., 2010). The ERA-I shows two distinct discontinuities: in 1985 from the transition from NOAA-7 SSU to NOAA-9 SSU and in August 1998 when ATOVS observing systems began to be assimilated. ERA-I assimilated both SSU and AMSU-A radiances until 2005. Channel 3 of the SSU prior to August 1998 and AMSU-A channel 14 were not bias corrected. After August 1998 the SSU channel 3 radiances were bias corrected (Simmons et al., 2014). MERRA merged the SSU and AMSU observations over a period of time. The version of the CRTM (Han et al., 2006) that MERRA used for other satellite radiances was not able to work with the SSU radiances, and as an alternative the GLATOVS (Susskind et al., 1983) was used. The latter was not updated with the necessary adjustments to the channels due to pressure cell leaks and changes in the stratospheric CO₂ concentration (Gelaro et al., 2017). MER-RA immediately stopped using the SSU channel 3 in October 1998 but continued to assimilate channels 1 and 2 through 2005. JRA-55 also merged the SSU and AMSU observations, but for a shorter overlap period of 1 year, and bias corrected all the SSU and AMSU-A channels (Kobayashi et al., 2015). MERRA-2 shows a discontinuity in 1995 from the transition from NOAA-11 to NOAA-14 SSU channel 3 radiances. A second discontinuity occurs when MERRA-2 immediately transitions from SSU and MSU to the AMSU in October

1998. A third discontinuity occurs when it begins using Aura MLS observations in August 2004. Just as with MERRA, MERRA-2 did not bias correct SSU channel 3 and AMSU-A channel 14. MLS temperatures were used to remove a bias in the upper stratosphere and to sharpen the stratopause (*Gelaro et al.*, 2017). *R1*, *R2*, and the 20CR reanalyses only extend up to 10hPa due to their fewer model layers, so the upper stratosphere is not analysed. *R1* and *R2* use NESDIS-derived temperature retrievals, which minimized satellite transitions. The 20CR is shown as an example that assimilated only surface-based observations. Therefore, it shows no discontinuities, but its forecast model included the volcanic aerosols and the historical changes in carbon dioxide to produce inter-annual variations in the stratosphere (see *Chapter 2* and *Fujiwara et al.*, 2017, for more details).

The timing and degree of these discontinuities will play a role in how well the various reanalyses compare with each other over time. Difficulties associated with assimilating the SSU observations due to their CO_2 pressure-modulated cells slowly leaking, and the changing of atmospheric CO_2 impaired the earlier reanalyses (ERA-40, JRA-25, MERRA). The more recent reanalyses should agree more closely with each other after 1998 because there are fewer issues assimilating the ATOVS, AIRS, and GPSRO observations (MERRA did not assimilate GPSRO data.)

The latest reanalysis (ERA5) exhibits several notable discontinuities, primarily in the middle and upper stratosphere. Similar to the ERA-I, ERA5 has a temperature discontinuity in 1985 from the transition from NOAA-7 SSU to NOAA-9 SSU and in August 1998 resulting from the transition from TOVS to ATOVS. *Simmons et al.* (2020) discusses these discontinuities and the apparent cold bias in the lower stratosphere beginning in 2000. ECMWF decided to rerun the period between 2000 and 2006 making several corrections. This corrected sub-reanalysis is called ERA5.1, which is now available.

Because of these discontinuities and transitions discussed above, reanalyses should be viewed very carefully for use in trend analysis and trend detection, especially in the middle and upper stratosphere.

3.4 Reanalysis ensemble mean (REM)

3.4.1 Methodology

No one reanalysis is the de facto standard for all variables and processes. Consequently a reanalysis ensemble mean (REM) of three of the more recent reanalyses (MERRA, ERA-I, and JRA-55) will be used as the reference from which differences and anomalies will be determined. The CFSR/CFSv2 is excluded from the REM primarily because of the streamchange impacts upon the temperature structure in the middle and upper stratosphere. MERRA-2 is not included in the REM because it had just become available at the time of the preparation of this chapter and does not include 1979. The data sets used to perform the intercomparisons are monthly mean zonal means at a 2.5° resolution. Standard post-processed pressure levels are used (1000, 850, 700, 500, 400, 300, 250, 200, 150, 100, 70, 50, 30, 20, 10, 7, 5, 3, 2, 1hPa). The focus time period of this intercomparison is 1979 through 2014. The current WMO 30-year climatology period (1981 - 2010) will be the base period of the climatology used. It should be noted that most reanalyses, with the exception of MERRA and MERRA-2, provide data below the surface for some regions (e.g., at 1000 hPa under Antarctica and the Tibetan Plateau). These data are calculated via vertical extrapolation. When the REM is created, re-gridded zonal means are first calculated for each reanalysis, and then the three data sets are averaged where valid data exist. Since most of the latitude zones poleward of 60°S are part of the Antarctic land mass with surface elevations reaching 3km, pressures higher than 700hPa have invalid data and hence are not analysed.

3.4.2 Climatology of the REM

3.4.2.1 Temperature

The seasonal variation in the REM temperature monthly means and their inter-annual variability as standard deviation (SD) in three different zonal regions (60° - 90°N, 10°S - 10°N, and 90° - 60°S) are shown in **Figure 3.2**. It is of note that at polar latitudes the lowest temperatures occur in the upper stratosphere in November (for the Northern Hemisphere, NH) and May (for the Southern Hemisphere, SH) and descend with time such that the lowest temperatures in the lower stratosphere do not occur until January in the NH and September in the SH. Thus, when lower stratospheric temperatures are reaching a minimum, upper stratospheric temperatures are already increasing.

Figure 3.2: Annual variation in the REM temperature monthly means (°C) and their Standard Deviation (K) in three different zonal regions: $60^\circ - 90^\circ N$ (a, b), $10^\circ S - 10^\circ N$ (c, d), and $90^\circ - 60^\circ S$ (e, f). Note in c and f contours cease at 700 mb due to Antarctic surface. Reproduced from Long et al. (2017).

Figure 3.3: Annual variation in the REM zonal wind monthly means ($m s^{-1}$) and their SD ($m s^{-1}$) in three different zonal regions: $40^{\circ} - 80^{\circ} N (a, b)$, $10^{\circ} S - 10^{\circ} N (c, d)$, and $80^{\circ} - 40^{\circ} S (e, f)$. Reproduced from Long et al. (2017).

The upper stratosphere polar circulation is well defined prior to solstice shutting down any meridional advection of heat into the polar region. Consequently, radiative cooling drives the temperatures to their lowest values prior to solstice. The lowest temperatures occur at about 30hPa in both polar regions. However, the lowest SH polar temperatures are more than 15K colder than the lowest NH polar temperature. The interannual variability graphs show that the greatest variability in the NH temperatures is in the upper stratosphere in February when wave activity is most pronounced. In the SH the greatest variability occurs in October and November, associated with the winter to spring transition from low to high temperatures when wave activity becomes significant in that hemisphere. This variability is associated with how quickly that transition occurs. In some years the circulation over Antarctica is very zonal and stable, which prolongs the period of low temperatures in the polar latitudes. In other

years there may be greater wave activity transporting heat from the extra-tropics into the polar latitudes, thus shortening the period of low temperatures. In the tropics, the variability is much smaller than in the polar regions but is associated with the phase of the SAO and the QBO in the upper and middle stratosphere, respectively.

3.4.2.2 Zonal wind

The seasonal variation in the REM zonal wind monthly means and their inter-annual variability in three different zonal regions $(40^\circ - 80^\circ \text{N}, 10^\circ \text{S} - 10^\circ \text{N}, \text{ and } 80^\circ - 40^\circ \text{S})$ are shown in **Figure 3.3**. In the NH polar jet region $(40^\circ - 80^\circ \text{N})$ the maximum winds occur in the upper stratosphere in November and December, and the greatest variability occurs from December through March.

In the SH polar jet region $(80^{\circ}-40^{\circ}S)$ wintertime westerlies are about 30 ms^{-1} stronger than the wintertime NH westerlies. These stronger westerlies are due to the much weaker disruption of the polar vortex by the vertically propagating planetary-scale waves and the stronger temperature gradients. Similar to the temperature variability, the variability in the SH polar night jet between May and August is not as great as in the NH polar jet. The SH zonal wind variability increases during the final warming and transition from westerlies to easterlies as wave activity increases from August through November.

In the tropical upper stratosphere, there is a strong semi-annual oscillation (SAO; *Ray et al.*, 1998; *Smith et al.*, 2017, 2020) with maximum westerlies of up to 20 ms^{-1} at equinox and intervening easterlies during the solstice periods. There is a marked asymmetry in the amplitude of the easterly SAO phase, with amplitudes of -40 ms^{-1} to -50 ms^{-1} in the easterlies in December to February but only -20 ms^{-1} to -30 ms^{-1} in July–September.

The easterly SAO phase is believed to result from the advection of easterlies from the summer hemisphere by the Brewer–Dobson circulation (*Gray and Pyle*, 1987), and this asymmetry is consistent with the much stronger circulation in December to February associated with greater wave activity in the NH winter. In the equatorial mid-stratosphere where the QBO dominates, the climatological winds in the tropical middle stratosphere have mean easterlies of -5 ms^{-1}

to -10 ms^{-1} . Because of the quasi-biennial nature of the winds, the inter-annual variability is very large, peaking between 10 and 20hPa. The SAO wind transition in the upper stratosphere also shows a high amount of inter-annual variability.

Please consult *Chapter 11*: Upper Stratosphere Lower Mesosphere for a detailed analysis of the SAO.

3.4.2.3 Meridional and vertical winds

The zonal-mean meridional and vertical winds will be discussed into two layers of the atmosphere: the troposphere and the stratosphere. In the troposphere, the zonal mean vertical and meridional winds combine to form the Hadley, Ferrel, and Polar circulation cells. In the stratosphere, the vertical winds are much smaller compared to those in the troposphere due to the stable nature of the stratosphere. In Figure 3.4 we present the Eulerian mean meridional and vertical winds for January and July 30-year climatological conditions in the stratosphere and troposphere. Seasonally, the dominant Hadley circulation exists in the winter hemisphere, although the centre of upwelling is in the summer hemisphere. Figure 3.4b shows that in January the greatest upwelling occurring at 10°S and greatest downwelling at 20°N. Completing this circulation are strong northerly meridional winds at 10°N and 200hPa and southerly winds at 10°N between the surface and 850hPa. A weaker SH Hadley circulation extends from 10°S to 40°S.

Figure 3.4: 30 year climatology of REM vertical (mPa s⁻¹) [colours] and meridional (m s⁻¹) [isolines] winds for January-stratosphere (a), July-stratosphere (b), January-troposphere(c), and July troposphere (d). REM tropopause (solid red line) is shown in (b) and (d). Subtropical jet central location is denoted with a 'J'. Note: diagnostics presented are Eulerian means.

Figure 3.5: 30 year climatology of the mean REM vertical winds (mPa/sec) between 700-200 hPa for January (a) and July (b).

Ferrel circulations extend from 20°N to 60°N and 40°S to 60°S. Polar circulations extend from 60°N to 80°N and 60°S to 80°S. There is slight upwelling over both poles. The ensemble mean tropopause is overlaid upon these wind fields and shows that in January it descends rapidly between 20°N and 30°N where the convergence of the NH Ferrel and Hadley circulations occur. The NH subtropical jet is located at this point of convergence and steep tropopause gradient. The tropopause descent in the SH is more gradual and the SH subtropical jet is not as strong. In July the circulation patterns are nearly opposite that of January: the SH Hadley circulation is dominant with the centre of upwelling moving northward to 10°N and the descending branch centred at 20°S. The NH Hadley circulation is much weaker; the locations of the Ferrel and Polar circulations are about in the same locations. The tropopause descends most rapidly in July between 20°S and 40°S, the SH subtropical jet is intensified, while the NH subtropical jet is weaker.

In the stratosphere, the vertical winds are much lighter with Eulerian ascending winds occurring poleward of the polar jet axis and descending winds occurring equator-ward of the polar jet axis. Very slight upward motion occurs in the summer hemisphere tropics. Eulerian meridional winds increase with altitude in the winter hemisphere with equator-ward winds between the regions of ascending and descending vertical winds and poleward winds occurring on the winter hemisphere side of the SAO easterlies. The convergence near the stratopause and associated descending winds and ascending polar winds are stronger in the NH winter than in the SH winter. A more in-depth analysis of these winds which includes the Transformed Eulerian Mean residual circulation (Andrews et al., 1987) is presented in Chapter 11 (Upper Stratosphere and Lower Mesosphere). Chapter 5 (Brewer-Dobson Circulation) provides greater detail about the stratospheric mean meridional circulation.

A global analysis of the ensemble mean tropospheric vertical velocities for January and July between 700 hPa and 200 hPa are shown in **Figure 3.5**. The analyses illustrate that

the zonal mean Hadley circulation depiction is dominated by the convection and upward vertical winds over the Western Pacific and Indian Ocean. The longitudinal band of upward vertical velocities in the tropics represents the Intertropical Convergence Zone (ITCZ). The analysis for the January climatology shows that over Africa, South America, the Indian Ocean and Western Pacific Ocean the maximum upward velocities are south of the Equator. The Atlantic and Eastern Pacific ITCZ bands are north of the Equator. In July, the centres of convection and resulting upward vertical velocities over the Indian Ocean and Western Pacific have moved north of the equator, while the Atlantic and Eastern Pacific bands have moved slightly further to the north. These differences in latitudinal location of upward velocities will impact the longitudinal make-up of the Hadley Circulation and the height and location of the tropopause. Greater details about the tropical circulation patterns, cross tropopause flow, the tropical cold point are provided in Chapter 8 (Tropical Tropopause Layer).

The longitudinal location of greatest convection and upward velocities that make up the Walker circulations varies with the state of the El Niño Southern Oscillation (ENSO). Under neutral conditions upward velocities are located over Africa, Western Pacific and Western Atlantic. Descending centres are located in the Arabian Sea, and over the Eastern Pacific. Under La Niña conditions, the convection and upward velocities over the Western Pacific and Western Atlantic are enhanced, while the descending motion over the Eastern Pacific is enhanced. The weaker ascending and descending circulations over Africa and the Arabian Sea, respectively, are replaced by a single strong descending circulation. Under El Niño conditions, the convection over the Pacific moves toward the middle Pacific. Enhanced convection and ascending motion occur over Africa. Descending motion occurs over the Western Pacific and Western Atlantic. Figure 3.6a shows a time sequence of the 10°N-10°S average ensemble mean vertical velocities at all longitudes between 700-250hPa. The characteristic longitudinal locations of ascending and descending velocities agree with the above statements. **Figure 3.6b** shows the deseasonalised anomalies, which more clearly shows the major El Niño occurrences of 1984, 1988, 1993, 1998, 2003, 2010, and 2016. La Niña events are harder to pick out since they are close in characterization to neutral conditions. The La Niña event following the 1998 El Niño does show the descending winds over Africa and enhanced ascending velocities over the Western Pacific. There are some time dependent changes from the TOVS to ATOVS periods that show up in the anomalies. Between 10°E and 30°E there is a change from negative anomalies during the 1980's and 1990's to positive anomalies after 2000.

3.4.3 Agreement among the REM members

3.4.3.1 Temperature

The previous section dealt with the mean of three of the more recent reanalyses (MERRA, ERA-I, and JRA-55). Now we examine their variability or "degree of disagree-

ment" over time. We define the degree of disagreement as the SD of the three reanalyses for each month, for each latitude zone, and for each pressure level for the 1979-2014 period. Latitude zones (*e.g.* 60° - 90°) are the cosine-weighted summations of the 2.5° zonal SDs. We must note that agreement of the three reanalyses does not imply correctness because the three reanalyses could possibly have similar erroneous analyses. For some months in the upper stratosphere, the temperature disagreement can be greater than 5K. Figure 3.7 presents pressure versus time series plots of the temperature SD (K) of the three members of the ensemble. Figure 3.7 shows how the monthly temperature disagreement varies in three latitude zones (60°N-90°N, 10°S-10°N and 90°S-60°S) in a time versus pressure plot. The mid-latitude plots are not shown but evaluations will be presented below. In all three latitude bands the disagreements are greatest at pressures lower than 10 hPa at which there are fewer conventional observations available for assimilation and the satellite observations generally have very broad weighting functions in the vertical. See Chapter 2, Figure 2.16 to see the vertical extent of satellite channels. The 60°N - 90°N plot shows that at pressures greater than the 20 hPa level, all three reanalyses

agree with each other very well, with an SD smaller than 0.5 K. Generally, from 1979 to 2001 the pressure at which the 0.5 K difference contour occurs stays constant between 20 hPa and 10 hPa. Interrupting this period during the 1990s, the NH polar activity was unusually quiet and cold (*Charlton and Polvani*, 2007; *Pawson and Naujokat*, 1999). Then from 2001 to 2014 the pressure at which the 0.5 K contour occurs moves upward to between 7 hPa and 5 hPa. The increased agreement between 20 hPa and 7 hPa is most likely due to the assimilation of AMSU and AIRS observations. The disagreement among the three reanalyses is greater in June–August than in other months due to the ERA-I having warmer temperatures at this level than MERRA and JRA-55.

In the tropics, the disagreement maximizes in two separate layers: between 150hPa and 70hPa during the TOVS period (1979–1998) and above 20hPa throughout the entire 1979–2014 period. The former disagreement is at the vertical location of the cold point temperature. Apparently, there is greater disagreement among the three reanalyses in determining this temperature during

Figure 3.6: Hovmöller diagram of (a) the 10° N - 10° S average REM vertical velocities (mPa/sec) at all longitudes from 1979 (top) through 2017 (bottom) between 700 - 250 hPa. (b) Hovmöller diagram of the deseasonalized 10° N - 10° S average REM vertical velocity anomalies (mPa sec⁻¹).

the TOVS period than during the ATOVS period. During the TOVS period there are only four MSU channels sounding the troposphere and lower stratosphere. The AMSU-A instrument has five channels (5 through 9; 1 through 4 are water vapour channels) sounding the same layer. These additional channels provide information about the temperature structure near the tropopause, thus allowing the reanalyses to better analyse and agree upon the temperature structure there. The pressure at which the greatest differences (3-4K) occur is 2 hPa and has a seasonally varying pattern.

In the 90°S-60°S zone, the disagreement among the three reanalyses extends lower into the stratosphere than the NH polar zone. This region encompasses all of Antarctica and the ocean surrounding it. There are very few observation sites in this latitude zone. *Manney et al.* (2005) and *Lawrence et al.* (2015) have shown that

reanalyses of temperatures in the polar stratosphere can differ significantly depending on what observations are available. Differences greater than 0.5 K during the TOVS period extend to 70 hPa. There are two layers of greatest disagreement in the TOVS period: between 7 hPa and 5 hPa and above 3 hPa. The disagreement between 7 hPa and 5 hPa terminates after 2001, which may be due to the assimilation of AIRS radiances.

The northern mid-latitude $(30^{\circ} N - 60^{\circ} N)$ disagreement (not shown) does not change significantly throughout the entire 1979 - 2014 period. Values larger than 0.5 K begin at pressures lower than 7 hPa and have summertime peaks of 2 K at pressures lower than 3 hPa.

The southern mid-latitude $(60^\circ\text{S}-30^\circ\text{S})$ disagreement (not shown) is similar to the SH polar disagreement in that the disagreement during the TOVS period extends to

Figure 3.7: Pressure versus time plots of the temperature SD (K) for each month of the three reanalyses making up the REM for three zonal regions: 60°N-90°N (a), 10°S-10°N (b), and 90°S-60°S (c). Reproduced from Long et al. (2017).

higher pressures (between 20 hPa and 30 hPa) than during the ATOVS period (between 7 hPa and 10 hPa). Also similar to the SH polar region, there are two layers of greatest disagreement in the TOVS period between 7 hPa and 5 hPa and above 3 hPa. The 7 hPa to 5 hPa layer disagreements also terminate after 2001, just as in the SH polar region.

3.4.3.2 Zonal winds

Figure 3.8 presents pressure versus time series plots of the zonal wind SD (m s⁻¹) of the three members of the ensemble mean. **Figure 3.8** shows the disagreement of the monthly ensemble members' zonal wind in the polar jet regions ($40^{\circ}N - 80^{\circ}N$ and $80^{\circ}S - 40^{\circ}S$) and in the tropics ($10^{\circ}S - 10^{\circ}N$). As with the temperatures, the zonal wind disagreement in the mid-latitudes are not shown but are described in the text below. There is very good agreement

of the zonal winds among the three reanalyses in the NH and SH polar jet regions with SDs smaller than 0.5 m s^{-1} . In the NH polar jet region, significant disagreement (> 0.5 m s^{-1}) among the three reanalyses is consistently confined to pressures lower than 5hPa. Disagreements greater than 0.5 ms^{-1} are nearly eliminated after the transition to ATOVS observations occurs at the end of 1998.

The altitude range of disagreement greater than $0.5 \,\mathrm{m\,s^{-1}}$ in the SH polar jet region extends from the upper stratosphere down into the middle stratosphere (10-20 hPa) during the TOVS time period, but improves considerably in the ATOVS time period.

The tropical zonal wind disagreement shows much larger values of the order of 10 m s⁻¹ in the upper stratosphere than the polar jet values, resulting from disagreement in SAO and QBO winds and winds near the surface at 850 hPa. There is

0.0 0.5 1.0 1.5 2.0 3.0 4.0 5.0 6.0 7.0 8.0 9.0 10.0 11.0 12.0

Figure 3.8: Pressure versus time plots of the zonal wind SD (m s⁻¹) for each month of the three reanalyses making up the REM for three zonal regions: 40° N - 80° N (a), 10° S - 10° N (b), and 80° S - 40° S (c). Reproduced from Long et al. (2017).

improvement with time in the agreement of the QBO winds and 850 hPa winds, but this improvement does not extend to the SAO height region. The greater improvement in the NH and SH polar jet winds after 1998 versus minor improvement in the equatorial winds illustrates the differences between the mechanisms controlling these winds. The polar jet winds are largely dictated by the latitudinal thermal gradient and resulting thermal wind. However, in the tropics the thermal wind relation breaks down and the wind fields are not well constrained by the assimilated satellite radiances. Alternatively, geostrophic winds using the geopotential can be used to derive the equatorial wind. (Smith et al., 2017). In addition, the tropical winds are primarily determined by the transfer of momentum from upward-propagating waves with spatial scales that are too small to be adequately resolved by the forecast models used in these reanalyses (Baldwin et al., 2001). The tropical winds are therefore highly dependent upon radiosonde observations for speed and direction (and these only extend to 10hPa). In general the amplitude of the reanalysis tropical winds are smaller than observations. Following the change to ATOVS data, the differences among the reanalyses decrease slightly. No single forecast model included in the REM is capable of generating a QBO on its own. To date, only the forecast model used in MERRA-2 is capable of doing so, and Coy et al. (2016) show that after 2000 the MERRA-2 QBO winds are greatly improved versus those in MERRA. It should also be noted that the SAO and polar night jets extend well into the mesosphere (Smith et al., 2020) and reanalyses with higher model tops may produce better results in the upper stratosphere than the lower top reanalysis models.

The characteristics of the NH and SH mid-latitude regions $(20^{\circ}N-40^{\circ}N \text{ and } 40^{\circ}S-20^{\circ}S$, respectively; not shown) are very similar to their respective polar jet regions. The NH mid-latitude disagreements during the TOVS period occur at pressures lower than 7hPa and do not exceed 1.5 m s⁻¹. During the ATOVS period the disagreements are more sporadic and occur at pressures lower than 3hPa.

The SH mid-latitude disagreement (not shown) occurs at pressures lower than 20 hPa during the TOVS period with values not exceeding 4 m s^{-1} . During the ATOVS period the disagreements become more sporadic, smaller in value, and occur at pressures lower than 7 hPa.

3.5 Intercomparisons of the reanalyses

In this section we extend our evaluation to the individual reanalyses and examine how each of eight reanalyses (CFSR/CFSv2, MERRA, ERA-I, JRA-55, MERRA-2, JRA-25, ERA-40, and *R1*) differs from the REM for both temperatures and winds. We do not show comparisons of *R2*, but one can expect all *R2* qualities to be nearly the same as those of *R1*. We also do not show comparisons with the 20CR as that reanalysis assimilated no upper-air observations. As a result, the 20CR does not show any QBO features in the tropical winds or temperatures, does not observe the occurrences of sudden stratospheric warmings making NH winters 5 K colder and polar zonal winds stronger than they should, and is 3 K-4 K warmer at 100 hPa in the tropics, which may be due to its coarse model vertical resolution.

3.5.1 Temperature

Figures 3.9 – 3.11 present the time-mean zonal mean temperature difference from the REM (reanalysis - REM) for each month (left columns). The right columns show the time series of the zonal-mean monthly mean differences from 1979 through 2014. The left columns show the average monthly mean differences, while the right columns show the monthly differences over time. Both are useful to illustrate where in the vertical and when in the annual cycle the differences occur and whether these improve over time. Differences in the right column typically do not extend throughout the entire 1979 - 2014 period. Rather, much like the other differences discussed earlier, large improvements are seen going from the TOVS to ATOVS time periods, with the TOVS time period having the larger differences extending down further from the upper stratosphere into the middle stratosphere. Except where specifically mentioned, temperature differences between the individual reanalyses and the REM are within 0.5 K. In general the earlier reanalyses (JRA-25, ERA-40, and R1) show greater differences from the REM than the more recent reanalyses (MERRA-2, MERRA, ERA-I, JRA-55, and CFSR/CFSv2). Also, the NH and SH polar latitudes generally show similar difference patterns, with much greater differences in the SH. Thus, in the following, we start with the description on the SH polar latitudes, then mention the NH polar latitudes relatively briefly, and finally describe the equatorial latitudes where the patterns are quite different from those at higher latitudes.

3.5.1.1 SH polar latitudes

MERRA-2 has a year-round cold bias of -1 K to -2 K compared to the REM from 1 hPa to 2 hPa, a year-round the warm bias from 3 hPa to 5 hPa, and a cold bias at 10 hPa from March through June. The time series shows that these biases are largest during the TOVS period, with much smaller differences during the ATOVS period, and that any bias is greatly reduced after August 2004 when Aura MLS temperatures at pressures less than 5 hPa are assimilated.

MERRA shows a warm bias of 1 K to 2 K in the time-mean plot compared to the REM between 2hPa and 3hPa from July through February. Below this, between 5hPa and 20hPa, there is a cold bias of -1 K to -2 K from April through August. The time series plot shows that this cold bias only exists during the TOVS period, while the warm bias at higher altitudes persists throughout the entire period.

The ERA-I has a mixture of cold (-1 K, March through August) and warm (2 K, November through February) biases compared to the REM between 1 hPa and 3 hPa. An

Figure 3.9: Pressure versus month plots (*a*-*h*) and pressure versus time plots (*i*-*p*) of the temperature difference (K) in individual reanalyses from the REM for the zonal region 90° S-60° S. The reanalyses are (*a*, *i*) MERRA-2, (*b*, *j*) MERRA, (*c*, *k*) ERA-I, (*d*, *l*) JRA-55, (*e*, *m*) CFSR/CFSv2, (*f*, *n*) JRA-25, (*g*, *o*) ERA-40, and (*h*, *p*) R1. The left column plots are the monthly mean differences for the entire 1979-2014 period. The right column plots are each month's difference from the REM for that same month. Reproduced from Long et al. (2017).

opposite set of biases exist slightly below, between 5hPa and 10hPa, during roughly the same time periods. The time series plot shows that the upper stratosphere cold bias exists during the 1990s. The upper stratosphere warm bias occurs after 1998, while the warm bias between 10hPa and 5hPa persists throughout the entire TOVS period.

The JRA-55 shows a cold bias (-2K to -4K) compared to the REM between 1 hPa and 5 hPa from July through March, which then descends to 7 hPa as a warm bias forms between 1 hPa and 2 hPa from March through June. The time series plot shows that temperature differences transitioned from the TOVS to ATOVS period with the cold bias of -4K to -6K becoming the dominant feature during this later period.

The CFSR/CFSv2 temperatures are 6K-8K warmer than the REM in the upper stratosphere, peaking during the period of minimum temperatures in that region between March and July. Just below this warm region, there is a small altitude region with colder temperatures than the REM of -1 K and -2 K. The time series plot shows that the CFSR/CFSv2 upper stratospheric warm bias occurs throughout the entire 1979-2014 time span with similar seasonal variability.

The JRA-25 time-mean plot shows greater differences from the REM than the above five reanalyses, with a year-long warm bias (8 K to 10 K) compared to the REM from 1 hPa to 3 hPa and a very cold bias (-4 K to -6 K) during the SH winter period between 5 hPa and 10 hPa. In the middle stratosphere there are periods of persistent cool bias with a maximum (-2 K to -4 K) occurring in the August–November months. The time series plot shows that the upper stratosphere warm bias (8 K to 12 K) persists throughout the entire time period, with greater values (>12 K) in the TOVS period. The cold bias (ranging between -2 K and -10 K) just below the warm bias occurs mostly during the ATOVS time period. The middle stratosphere cold bias (-2 K to -6 K) occurs during the TOVS period (see Section 5.2 of Fujiwara et al., 2017, for the reason).

The ERA-40 time mean plot shows a strong cold bias (-2K to -6K) compared to the REM persisting year-long between 2hPa and 10hPa. Just below this is a warm bias (2K-4K) between 10hPa and 30hPa. The annual cycle of both the cold bias and warm bias show a slight rising in summer and a lowering in winter months. In the lower stratosphere and upper troposphere, there are layers and monthly periods of slight cold (> -2K) and slight warm (<2K) bias. The time series plot shows that these biases occur throughout most of the ERA-40 time period, which ends in 2002.

R1 does not analyse at pressures lower than 10 hPa, so there is no evaluation in the upper stratosphere. However, there is a nearly year-round warm bias (1 K to 2 K) compared to the REM between 10 hPa and 50 hPa peaking between June and September. Another shallow layer of warm bias (1 K to 2 K) exists between 100hPa and 400hPa. The time series plot shows that the middle stratospheric warm bias is most pronounced in the TOVS period.

3.5.1.2 NH polar latitudes

Many features in the upper stratosphere are common for their respective seasons between the NH and SH polar latitudes (Figure 3.10). However, differences with the REM in the middle and lower stratosphere in the SH are reduced or eliminated in the NH. The cold bias that occurred between 10hPa and 5hPa in the MERRA-2 differences during the SH winter season is not present in the NH winter differences. MERRA differences from the REM in the NH are much smaller in the monthly means, with just a thin warm bias layer between 3hPa and 5hPa. The time series shows only slight differences in the middle and lower stratosphere during the TOVS period compared to the same altitude region in the SH. The ERA-I and JRA-55 have very similar seasonal biases as those that occurred in the SH. Similar to MERRA, the time series of differences for the ERA-I during the TOVS period in the middle and lower stratosphere are nearly eliminated. The JRA-55 time series does not have noticeable differences from what was observed in the SH. The CFSR/CFSv2 wintertime warm bias that occurs at pressures lower than 7hPa extends from October through March. There is no evidence of a cold bias underneath this warm bias in the monthly means as occurs in the SH. The time series of differences shows that the differences that occur in the middle and lower stratosphere in the SH do not exist in the NH. The JRA-25, ERA-40, and R1 all show similar seasonal biases from the REM in the upper stratosphere. Their time series show reduced differences in the middle and lower stratosphere.

3.5.1.3 Equatorial latitudes

Differences in reanalysis temperatures from the REM in the equatorial regions (10°S-10°N) vary more on a semi-annual basis. Figure 3.11 shows that such is the case for the CFSR/CFSv2 upper stratosphere warm bias of 2K to 4K and for the JRA-55 upper stratosphere cold bias of -2 to -4 K. MERRA-2 shows relatively small differences (<1K) at all altitudes compared to the REM and the near elimination of any bias after August 2004 when MLS temperatures at pressures less than 5 hPa were assimilated. The MERRA and ERA-I exhibit a slight warm bias at pressures lower than 5hPa. The time series plots for the CFSR/CFSv2 show the jumps associated with the different streams and the gradually increasing warm bias in the upper stratosphere during each of these streams. A warm bias centred at 100 hPa and a cold bias below persist though the TOVS period. The MERRA and ERA-I have temperature biases that are greater during the TOVS period than the ATOVS period. In the ATOVS period the bias in both reanalyses is confined to the upper stratosphere at pressures less than 3hPa with a warm bias of 0.5K to 2K. The JRA-55 reanalyses show

Figure 3.10: Same as Figure 3.9 but for the 60° N – 90° N latitude zone. Reproduced from Long et al. (2017).

Figure 3.11: Same as Figure 3.9 but for the 10°S – 10°N latitude zone. Reproduced from Long et al. (2017).

that the cold biases are nearly constant throughout the entire time series. The JRA-25 has a consistent warm bias of 4K to 6K in the upper stratosphere at pressures less than 3 hPa. Immediately below this at 5 hPa is a cold bias of -2 K to -8K that is largest during the ATOVS period. Between 30 hPa and 50 hPa, there is another layer of cold bias of -2 K to -6K that is present only during the TOVS period. ERA-40 has a persistent cold bias of -2K to -6K in the upper stratosphere between 2 hPa and 7 hPa and two layers of warm bias of 0.5K to 1K in the middle stratosphere and tropopause regions. R1 in the middle stratosphere has slight warm and cold biases associated with the QBO (seen in the time series plot). There is also a persistent warm bias of 2 K to 4 K in the upper troposphere to tropopause layer between 70 hPa and 200hPa. This warm bias persists from the TOVS period to the ATOVS period when its magnitude decreases to a warm bias of 1K to 2K. Randel et al. (2004) pointed this out in their comparison of analyses and attributed the inability to capture lower tropopause temperatures to the coarse vertical resolution and the assimilation of retrieved temperatures (as opposed to radiances).

As discussed in *Section 3.4.3* the three members of the ensemble mean have their greatest disagreement in the upper stratosphere. From the above differences compared to the REM temperatures, the upper stratospheric warm bias of MERRA and ERA-I at all latitudes is nearly counterbalanced by the cold bias of the JRA-55. The ERA-I warm bias between 5 hPa and 7 hPa in the SH polar latitudes is counterbalanced somewhat equally by the MERRA and JRA-55 reanalyses.

3.5.1.4 NH and SH mid-latitudes

The NH and SH mid-latitude zone $(30^{\circ}N-60^{\circ}N)$ and $60^{\circ}S-30^{\circ}S$, respectively) monthly mean temperature differences and time series temperature differences (not shown) are nearly exactly the same in character, altitude, and value as the respective polar region differences.

3.5.2 Zonal wind

3.5.2.1 SH polar latitudes

The time-mean SH polar jet differences (see the supplement of *Long et al.* (2017); not shown) of the individual reanalyses from the REM are relatively small, ranging from -2 m s^{-1} to 1 m s^{-1} , with most differences smaller in magnitude than that. As presented in *Section 3.4.3.2*, the REM members agree quite well in the polar jet region in both hemispheres. Some notable features are as follows. For all reanalyses except *R1*, the upper stratosphere is the region where the greatest differences from the REM are seen, but shows much improvement from the TOVS to ATOVS periods. MERRA-2 shows further improvements after 2004 when the MLS temperatures started to be assimilated at pressures less than 5 hPa. JRA-25 and ERA-40 show greater differences compared to more recent reanalyses. Finally, *R1* shows an easterly bias to the westerlies during the transition months from westerlies to easterlies in the middle and lower stratosphere for most of the entire time series.

3.5.2.2 NH polar latitudes

Just as with the NH temperature differences in *Section 3.4.1.2*, the NH polar jet wind differences from the REM (see the supplement of Long et al. (2017); not shown) are smaller in magnitude than the SH differences and are restricted mainly to the upper stratosphere.

3.5.2.3 Equatorial latitudes

In Figure 3.12, differences in the stratosphere at pressures less than 7 hPa show how the reanalyses differ from each other in the strength of the westerly and the easterly phases in the SAO region. CFSR/CFSv2 and JRA-55 have weaker westerlies and thus have negative biases of greater than -5 ms⁻¹ during the March-April and September-November westerly periods. They also have positive biases greater than 3 m s⁻¹ during the December – February easterly period. MERRA and ERA-I have stronger westerlies and show positive biases of greater than 3 m s⁻¹ during the March – April and September - November westerly periods. They also have stronger easterlies during the December-February period but differ slightly during the July-August easterly period. This results in the MERRA and ERA-I having negative biases of less than -3 m s⁻¹ during the former period. The SAO westerlies in MERRA-2 are more than 10 m s⁻¹ stronger than those in the REM. The time series shows that the stronger westerlies occur primarily during the TOVS period. Kawatani et al. (2016) and Molod et al. (2015) note that the downward-propagating westerly phase of the SAO is enhanced during the 1980s and could be caused by strong gravity wave forcing.

MERRA-2 also transitions from QBO westerlies to easterlies more rapidly than the REM during the TOVS period. The time series plots also show where each reanalysis has a slight easterly or westerly bias associated with the phase of the descending QBO winds. The JRA-25 and R1 show greater differences from the REM than the other reanalyses. *R1* shows a westerly bias of $>4 \text{ m s}^{-1}$ during the easterly phase of the QBO from 10 hPa down to 100 hPa. This was also discussed by Pawson and Fiorino (1998b). The JRA-25 has an easterly bias of $>4 \,\mathrm{m \, s^{-1}}$ during the easterly phase of the QBO from 10hPa down to 30hPa. It should be noted that the CFSR/CFSv2 used ERA-40 zonal winds as substitute observations between 30° S and 30° N and from 1 hPa to 30 hPa from 1 July 1981 to 31 December 1998 (Saha et al., 2010); hence their differences from the REM during that time period and in that pressure range are very similar.

Interestingly, in **Figure 3.12** there are also sizable differences in the troposphere. The CFSR zonal winds in the tropical

Figure 3.12: Pressure versus month plots (a - h) and pressure versus time plots (i - p) of the zonal wind difference (m s⁻¹) in individual reanalyses from the REM for the zonal region 10 °S–10 °N. The reanalyses are (a, i) MERRA-2, (b, j) MERRA, (c, k) ERA-I, (d, l) JRA-55, (e, m) CFSR/CFSv2, (f, n) JRA-25, (g, o) ERA-40, and (h, p) R1. Reproduced from Long et al. (2017).

upper troposphere during the TOVS years have an easterly bias. This may be associated with the CFSR having a cold bias of about 1 K in the upper troposphere during this time period. The JRA-55 zonal winds have a westerly bias during this time period. The MERRA and ERA-I zonal wind differences in the upper troposphere are no larger than 0.5 m s⁻¹. Hence, the differences from the REM show that the CFSR has a consistent layer of negative biases of -1 m s⁻¹ to -2.5 m s⁻¹ from 50hPa to 300hPa. The JRA-55 shows the other extreme of a consistent positive bias of 1 m s⁻¹ to 2 m s⁻¹ from 30 hPa to 200 hPa. The time series plots confirm that these upper troposphere zonal wind biases are persistent during the TOVS time period and are reduced in the ATOVS period. MERRA-2 shows large positive differences of >6 m s⁻¹ from the REM in the upper stratosphere (SAO region). The time series show that these large differences occur mostly during the 1980s and periodically extend to 20hPa. These large differences continue throughout the time series but are confined to the upper stratosphere after the 1990s.

3.5.2.4 NH and SH mid-latitudes

Characteristically, the zonal winds in the NH and SH mid-latitudes (20°N-40°N and 40°S-20°S, respectively; not shown) are different depending upon the altitude. In the troposphere there is the subtropical jet with maximum winds near 200hPa. In the lower stratosphere there is a lull between the equatorial winds and the polar jet. The upper stratosphere is seasonally transitioning from the SAO to the winter polar jet. The differences from the REM show that all the reanalyses are in very good agreement with the tropospheric subtropical jet. In the lower stratosphere *R1* has a westerly bias of $0.5 \,\mathrm{m\,s^{-1}}$ to $1 \,\mathrm{m\,s^{-1}}$, which is greatest in the early 1980s and diminishes to nil by the 2000s. The CFSR/CFSv2, interestingly, has an easterly bias of -0.5 ms⁻¹ to -1 ms⁻¹ during the TOVS period and is eliminated in the ATOVS period. All the other reanalyses are in good agreement (differences within $\pm 0.5 \,\mathrm{m\,s^{-1}}$) with the REM in the lower stratosphere. In the middle stratosphere the JRA-25 has differences between -0.5 ms⁻¹ and -1 ms⁻¹ from the REM in both the NH and SH mid-latitudes. In the upper stratosphere the more recent reanalyses have differences between -1 ms-1 and 1 ms⁻¹ from the REM, which diminish further during the ATOVS period. The JRA-25 and ERA-40 have slightly larger differences, which also diminish appreciably in the ATOVS period.

3.5.2.5 Comparisons with Singapore QBO winds

Kawatani et al. (2016) provides a thorough evaluation of the RMS differences in QBO (70hPa-10hPa) zonal winds among the more recent reanalyses and observations from all the radiosonde sites in the equatorial-latitude zone. Kawatani et al. (2016) also show that of the nearly 220 radiosonde stations in the 20°S - 20°N zone, Singapore (1°N, 104°E) is the only station that reports 10hPa observations 80-100% of the time between 1979 and 2001. For this reason, we will focus just upon comparisons between the reanalyses and zonal winds at Singapore. This is not to imply that Singapore is representative of the entire tropical zone. There is longitudinal variability in the zonal-mean zonal winds (Kawatani et al., 2016). Figure 2 of Kawatani et al., 2016 shows that the RMS differences between the various reanalyses and the Singapore wind observations declines over the 1979-2011 time period. Correlations among the monthly mean MERRA-2,

Figure 3.13: RMS differences (m s⁻¹) (a - c) and linear slopes (d - f) of the matched QBO zonal wind anomalies at 70, 50, 30, 20, and 10 hPa for the CFSR/CFSv2, MERRA, ERA-I, JRA-55, and MERRA-2 reanalyses interpolated to Singapore (1° N, 104° E) versus the observed Singapore monthly mean zonal winds from the FUB. RMS differences and slopes are computed for the 1980-2014 time period (a, d), the 1980-1998 period (b, e), and the 1999-2014 period (c, f). Slopes less than 1.0 indicate that the reanalysis zonal winds are weaker than the Singapore zonal winds. Reproduced from Long et al. (2017).

MERRA, ERA-I, JRA-55, and CFSR/CFSv2 QBO zonal winds (interpolated to Singapore) and the monthly mean radiosonde wind observations at Singapore (obtained from the Free University of Berlin) are mostly above 0.9. More information about how the reanalyses differ from the Singapore winds can be obtained by evaluating the linear regression line between the observed and analysed QBO winds and their scatter. Figure 3.13a-c shows the RMS differences in the reanalyses QBO winds and those at Singapore. Comparisons are shown for the entire 1980-2014 period and then divided into the TOVS (1980-1998) and ATOVS (1999-2014) periods. All of the reanalyses RMS differences are smaller during the ATOVS period. All of the RMS differences increase from 70hPa to 10hPa as does the amplitude of the winds at these levels. The RMS differences decrease by one-half to one-third from the TOVS to the ATOVS period. Of these five reanalyses, the CFSR/CFSv2 performs the poorest with higher RMS differences at nearly all pressure levels during all periods. MERRA-2 has the largest RMS differences at 10 hPa during the TOVS period, but improves during the ATOVS period. As seen in Figure 3.12, MER-RA-2 has large irregularities in the 1980s and in 1993. As mentioned earlier, these irregularities are a result of overly strong SAO westerlies that propagate down to the middle stratosphere. Coy et al. (2016) explain that during the 1980s and early 1990s MERRA-2 overemphasized the annual signal. Figures 3.13d-f show the slope of the regression line between the individual reanalysis QBO winds and the Singapore QBO winds. The maximum underestimation (slope smaller than 1) at 50hPa is present in all of the reanalyses. The reanalysis winds and Singapore winds become more similar in strength at lower pressure levels and are closer in strength during the ATOVS period than the TOVS period. The CFSR/CFSv2 has consistently weaker winds at all

Figure 3.14: Yearly annual temperature amplitude (K) for 90°S-60°S (a - e) and 60°N-90°N (f - j) from the (a, f) MERRA-2, (b, g) MERRA, (c, h) ERA-I, (d, i) JRA55, and (e, j) CFSR/CFSv2 reanalyses. Note that the SH annual amplitude is much larger than the NH amplitude. No analysis is performed between 1000 and 700 hPa for the SH plots as this is below the Antarctic surface. Reproduced from Long et al. (2017).

pressure levels during both the TOVS and ATOVS periods. No one reanalysis is better than the others at all QBO levels in either the TOVS or ATOVS period. Greater detail about the QBO is provided in *Chapter 9* (Quasi-Biennial Oscillation).

3.6 Amplitude of polar annual temperature cycle

Another way to examine the differences among the reanalyses is to compare their annual temperature amplitude (warmest summer month minus coldest winter month) in the polar latitudes. If a reanalysis has a wintertime warm bias or a summertime cold bias, then its annual temperature amplitude will be smaller compared to the other reanalyses. Generally, as **Figure 3.2** shows, the summertime temperatures do not vary much from year to year,

while the wintertime temperatures have greater inter-annual variability. The mean polar temperatures in Figure 3.2 indicate which months would likely be used as the warmest and coldest at the various pressure levels. For these differences we use the coldest (warmest) month from November through March and the warmest (coldest) month from May through September for the Northern Hemisphere (Southern Hemisphere). The lower variability in the SH temperatures ensures that the same months are used for the 1979 to 2014 period. However, in the NH the coldest month at a particular pressure level depends upon whether an SSW occurs. In the upper stratosphere, after an SSW the low temperatures following the warming are usually the lowest of the year. Without a warming the lowest temperatures may well have occurred in November or December. In the middle stratosphere the lowest temperatures will usually occur in December. In the lower stratosphere the lowest temperatures will usually occur in December or January. In Figure 3.14 a time series of the SH and NH polar zone annual temperature amplitudes is presented. In general, the SH annual amplitudes in the middle and upper stratosphere are up to 25 K larger than at the same level in the NH, largely because of the persistent and colder SH winters. At pressures greater than 300hPa, temperature amplitudes in the SH are smaller than those in the NH. SH temperature amplitudes increase from 5K-15K in the troposphere to

45K-60K in the middle stratosphere. Maximum amplitudes (60K-70K) in the SH occur above 10hPa. In the NH polar latitudes, the minimal amplitude of 5K-15K occurs at the polar tropopause. Between the surface and the tropopause, the temperature amplitude is larger at 15 K - 25 K. Above the tropopause the temperature amplitude increases up to about 2 hPa - 3 hPa where the temperature amplitude lies in the 55 K - 60 K range, although the depth of this layer is not nearly as extensive as in the SH polar regions. The depth of this variability below 10 hPa ends prior to 2002. The assimilation of GPSRO data beginning in 2002 could be the cause for this decrease in SH high latitude variability. There is good agreement among these five more recent reanalyses on the years of peak amplitude in the NH polar region upper stratosphere.The peak SH amplitudes of the five reanalyses are in lesser agreement in year and pressure range.

Figure 3.15: Pressure versus time plots of differences in reanalyses minus HIRDLS temperatures (K) from January 2005 through January 2008 for the Southern Hemisphere high-latitude zone (60° S). The reanalyses are (a) MERRA-2, (b) MERRA, (c) ERA-I, (d) JRA-55, and (e) CFSR/CFSv2. Reproduced from Long et al. (2017).

Individually, the five more recent reanalyses agree well with each other from the surface through the lower stratosphere in both hemispheres. However, the ERA-I shows an annual temperature amplitude in the middle stratosphere that is 5K-15K smaller than the other four reanalyses in the SH and about 5K smaller in the NH polar regions from 1979-2002. The JRA-55 has smaller maximum amplitudes in the SH than the other four reanalyses, which is associated with its seasonally low temperature bias in the upper stratosphere, whereas the CFSR/CFSv2 tends to have consistently large maximum amplitudes which are associated with its seasonally warm bias. However, the CFSR/CFSv2 temperature amplitudes peak at greater pressures in the upper stratosphere and then decrease rapidly between 3hPa and 1hPa in both hemispheres, particularly in the ATOVS period. This is most likely due to the fact that the CFSR/CFSv2 did not bias correct the SSU channel 3 observations and did not assimilate the top AMSU-A channel 14.

Figure 3.16: Same as **Figure 3.15** except for the Northern Hemisphere highlatitude zone (60° N - 80° N). Reproduced from Long et al. (2017).

As a group the NH plots show that the greatest amplitudes occur at 2 hPa. The years with this large amplitude are years in which an SSW occurred. This is a result of the very cold air that immediately follows the warming in the upper stratosphere. The years in which an SSW did not occur (e.g. the 1990s) have smaller temperature amplitudes in the upper stratosphere. The SH years in which there was a great amount of wave activity during the winter months had warmer winters and consequently smaller annual amplitudes. This is particularly noticeably in 2002 and 2010. These two years exhibited a very early transition from winter circulation to summer circulation, similar to a final warming in the NH. Final warmings are not followed by very cold air in the upper stratosphere. The ERA-I stands out as having smaller annual amplitudes in the SH middle stratosphere compared to the other four reanalyses during the TOVS period.

3.7 Comparisons with satellite temperature observations

3.7.1 HIRDLS and MLS temperatures

The NASA Earth Observing System (EOS) Aura spacecraft was launched in July 2004 and has several on-board instruments that measure multiple atmospheric constituents. The High Resolution Dynamics Limb Sounder (HIRDLS; Gille et al., 2008) instrument on the Aura spacecraft made measurements from the upper troposphere through the mesosphere until it prematurely ceased functioning in mid-2008. Quality temperature measurements extend from January 2005 through March 2008. The HIRDLS measurements were not assimilated by any of the reanalyses and thus are independent measurements. Monthly mean temperature differences in reanalyses from the HIRDLS (reanalysis - HIRDLS) temperatures at NH high latitudes (60°N-80°N), the tropics (10°S-10°N), and SH high latitudes (60°S) were generated for the 2005 through 2008 period. Figures 3.15-3.17 present the differences in MERRA-2, MER-RA, ERA-I, JRA-55, and CFSR/ CFSv2 from the HIRDLS monthly means for these latitude zones, respectively. The time, location, and amplitude of the SH differences are generally similar to those of the reanalyses from the REM (Figure 3.6).

MERRA-2 has a warm bias all year long at 1 hPa and a 1-2K cold bias from November through March. MER-RA has a cold bias of 2-4K from August through April at 1-3hPa and a 2K warm bias from May through July. ERA-I has a 2K cold bias at 2hPa from February through May. JRA-55 has a 4-6K cold bias from July through April between 2hPa and 3hPa that becomes thinner in altitude from April to July as a warm bias occurs from 1 hPa to 2hPa. The CFSR/CFSv2 has a very warm bias of over 14K in the April to July period at pressures lower than 5hPa with a cold bias at 7hPa during this same time period. All of the reanalyses show a slight (<1K) warm bias in the middle stratosphere during the November through March period.

In the NH, the cold bias of MERRA-2 in the summer period is smaller in the NH, while the year-long warm bias exists at 1 hPa. The cold bias that MERRA has in the SH

does not exist in the NH. The midwinter warm bias that was in the SH is about 1 K warmer in the NH. Similarly, the ERA-I does not have a cold bias in the late winter–spring period, but there is a warm bias in midsummer in the upper stratosphere. The CFSR/CFSv2 and JRA-55 differences with HIRDLS occur in the same seasons as in the SH with little change in amplitude. Of interest is that all the reanalyses show a similar warm bias as in the SH during the November through March period.

In the tropics, MERRA-2 continues to have a year-long warm bias at 1 hPa and a slight warm bias near 10 hPa. In 2006 - 2007 MERRA has a warm bias between 2hPa and 3hPa during January and February and moves lower to 5 hPa to 10 hPa during the other months of the year. ERA-I seems to have a year-long 0.5 K to 1 K warm bias at pressures lower than 10hPa. JRA-55 has a year-long 1-2K cold bias between 5hPa and 2hPa. The CFSR has a warm bias, similar to that at high latitudes, on a semi-annual basis in the upper stratosphere.

The Microwave Limb Sounder (MLS) is also on the EOS Aura spacecraft. Monthly zonal means of temperatures from the version 4 retrievals were provided by the MLS team for comparisons with reanalyses for the 2005–2014 period. The characteristics of the MLS temperatures are described by *Schwartz et* al. (2008) and Livesey et al. (2015). Note again that among the reanalyses, MERRA-2 is the only one that assimilated MLS temperatures but only at pressures less than 5 hPa. HIRDLS temperatures have been noted to be colder than the Aura MLS temperatures (Gille et al., 2008) in the upper stratosphere. Evidently, differences in MERRA-2, MERRA, ERA-I, JRA-55, and CFSR/CFSv2 temperatures from the MLS temperatures (not shown) are very similar to those with the HIRDLS but less positive. Differences greater than ±2K only occur above 10 hPa. Bands of differences of the order of 1 K are present below 10 hPa; however, the MLS documentation notes that there are known oscillations of this magnitude in comparison with other satellite temperature sensors, so these latter differences are not considered significant. Overall differences from the MLS observations are in agreement with the characteristics already described for each of these reanalyses.

Figure 3.17: Same as *Figure 3.15* except for the equatorial-latitude zone (10° S - 10° N). Reproduced from Long et al. (2017).

3.7.2 Comparisons with COSMIC temperature observations

COSMIC GPSRO monthly zonal mean dry temperatures from January 2007 through December 2014 (level 3, version 1.3) were obtained from the JPL GENESIS data portal. *Leroy et al.* (2012) explain the technique through which the RO observations were turned into temperatures and transposed from altitude to pressure surfaces. We use these data to compare against the MERRA-2, MERRA, ERA-I, JRA-55, and CFSR/CFSv2 monthly zonal mean temperature for the same period. The COSMIC data set provides temperature from 400 hPa to 10 hPa. We will not perform comparisons with data at pressures higher than 200 hPa as atmospheric water vapour causes deviations in the actual temperatures from the dry temperatures. **Figure 3.18** shows the 8-year time series of

differences (reanalysis - COSMIC) between the reanalysis temperatures and the COSMIC temperature in the SH polar latitudes (90°S-60°S). Most obvious is a recurring 1 K difference between the reanalyses and COSMIC from January through July from 10 hPa down to 100 hPa. This is during the transition from SH summer to winter. During the transition from SH winter to summer, there is a 0.5 K to 1K difference also extending from 10hPa to 100hPa. The source of these two biases could be in how the COS-MIC zonal mean temperatures are generated as there is a 3-5-day time averaging in which temporal transitions may be smoothed out. Also, Steiner et al. (2020) indicates that all GPSRO processing centres show greater uncertainties in their temperature product above 25km especially in the high latitudes. All of the reanalyses differed (except MERRA) in assimilating either the GPSRO bending angle or refractivity (Curcurull et al., 2007; Poli et al., 2010).

> Figure 3.19 shows the reanalysis minus COSMIC differences for the NH polar region (60°N-90°N). Similar negative differences occur during the transition from NH summer to winter. The depth and time length of the -1 K differences are smaller than the SH differences. There are also short-term negative differences that extend from 10 hPa to 100 hPa during the years in which an SSW occurred (2009, 2010, and 2013). In 2009 this is preceded by a short-term (1-month) positive difference also extending from 10 hPa to 100 hPa. The positive differences occur during the months when the SSW produced very warm temperatures in the NH polar region. The negative spikes occurred in the month(s) following the warming when very cold temperatures followed the warming in the upper and middle stratosphere. These differences imply that the dry temperature data set does not capture the maximum warming during the SSW or the cooling which follows. This may be due to the fewer COSMIC observations in the polar region versus the number of observations peaking between 50°N and 60°N in both hemispheres.

> Differences between the reanalyses and COSMIC dry temperatures in the tropics (10°S-10°N) (**Figure 3.17**) show much smaller negative differences. MERRA-2, JRA-55, and especially ERA-I show very few occurrences of differences exceeding -0.5 K.

The few differences with the JRA-55 have a seasonal occurrence from December through February. MERRA, which did not assimilate the GPSRO data, has negative differences fairly consistent between 10hPa and 30hPa. CFSR/CFSv2, which did assimilate GPSRO observations, has more occurrences of negative differences than MERRA-2, JRA-55, and ERA-I.

The NH and SH mid-latitudes (not shown) have seasonal differences similar to their respective polar regions but to a smaller time extent and shallower from 10 hPa down into the middle atmosphere. We conclude that between 60°S and 60°N, the lower stratosphere temperatures in the more recent reanalyses and the COSMIC dry temperatures are within ± 0.5 K of each other consistently throughout the year.

3.7.3 Atmospheric layer temperature anomalies

Long-term satellite observations from NOAA polar orbiting satellites of temperatures in the lower stratosphere (TLS) are available from the MSU-4 and AMSU-A9 microwave channels, while the Stratospheric Sounding Unit channel 1 (SSU1) and channel 2 (SSU2) provide temperature observations of the middle and upper stratosphere, respectively. Zou and Qian (2016) explain the process of merging and extending the infrared-based SSU observations with the microwave-based AMSU-A and ATMS observations. The satellite weighting functions for these three channels can be found in Chapter 2 (Figure 2.16) and Seidel et al. (2016, their Figure 1) and on the NOAA STAR SSU website (http://www.star.nesdis.noaa.gov/ smcd/emb/mscat/index.php). These satellite-observation climate data records have been used to compare with climate model runs to determine whether the model accurately captures the atmospheric vertical temperature changes since 1979 (Zhao et al., 2016). Other studies use these temperature data records to monitor changes in the Brewer-Dobson circulation (Young et al., 2011, 2012). Randel et al. (2016) compared global and latitudinal trends from SSU with Aura MLS and SABER temperatures. Simmons et al. (2014) discuss the impacts of the MSU, SSU, AMSU-A, HIRS, and AIRS channels assimilated in the ERA-I. Seidel et al. (2016) intercompared the TLS trends from three satellite centres

for the entire (1979-2015) period and separate trends for pre-1997 and post-1997. Mitchell et al. (2015) generated TLS and SSU channel-weighted temperatures from reanalyses to see how well they compare with the satellite observations. We perform a similar exercise by applying the TLS, SSU1, and SSU2 weights to the reanalyses temperatures at their standard pressure-level temperatures. Table 3.2 provides weighting function information about each of the SSU and MSU-4 channels. Chapter 2 (Figure 2.16) shows the vertical extent of the satellite channels. SSU3 layer temperatures were not generated because there were insufficient pressure levels from the majority of the reanalyses to adequately represent this layer in the lower mesosphere. Global mean TLS, SSU1, and SSU2 temperatures are generated for each month from 1979 through 2014. Anomalies from the 30-year period (1981 - 2010) for the TLS, SSU1, and SSU2 are generated. These anomalies are compared against the NOAA STAR SSU v2.0 data set (Zou et al., 2014) and MSU/AMSU mean layer atmospheric temperature v3.0 (Zou and Wang, 2012).

-12.0 -10.0 -8.0 -6.0 -4.0 -2.0 -1.0 -0.5 0.5 1.0 2.0 4.0 6.0 8.0 10.0 12.0 **Figure 3.19:** Same as **Figure 3.18** except for the Northern Hemisphere highlatitude zone (60° N - 90° N). Reproduced from Long et al. (2017).

The left column of **Figure 3.21** shows the monthly TLS, SSU1, and SSU2 temperature anomalies from the CFSR/CFSv2, ERA-I, JRA-55, MERRA, and MERRA-2 from 1979 through 2014 with the NOAA STAR anomalies overplotted in black. In general, the anomalies show that the layer temperatures were higher in the 1980s than at present. The El Chichón and Mt. Pinatubo volcanic eruptions increased the layer mean temperature by over 1 K from 1982 - 1984 and 1991 - 1993, respectively. Smaller impacts occurred in the SSU1 and SSU2 layer temperatures, as the volcanic influence was mostly in the lower stratosphere. The TLS temperature anomalies show a flat trend between the two volcanoes and after Mt. Pinatubo. The SSU1 and SSU2 temperature anomalies have a persistent cooling trend from 1979 to 2010 and have become flatter since then.

To better assess how each reanalysis differs from the NOAA STAR anomalies, the right column shows the differences in the anomalies of each reanalysis from the NOAA STAR anomalies. The reanalyses TLS anomalies differ from the

-12.0 -10.0 -8.0 -6.0 -4.0 -2.0 -1.0 -0.5 0.5 1.0 2.0 4.0 6.0 8.0 10.0 12.0 **Figure 3.20:** Same as **Figure 3.18** except for the equatorial-latitude zone (10°S-10°N). Reproduced from Long et al. (2017).

Table 3.2: Pressure (hPa) of SSU channels 1, 2, and 3 and MSU channel 4 weighting function peaks, 50% of peak weight above, 50% of peak weight below, 10% of peak weight above, and 10% of peak weight below the peak.

	Peak	50 % above	50% below	10 % above	10 % below
SSU Ch 3	1.5	0.5	5	0.15	45
SSU Ch 2	3.5	1.5	20	0.30	100
SSU Ch 1	15.0	4.5	60	1.10	150
MSU Ch 4	85.0	35.0	150	15.0	175

NOAA STAR anomalies by less than ± 0.5 K for most of the time series. Most noticeable is that the ERA-I has smaller anomalies than NOAA STAR in the early 1980s and then has larger anomalies after 2006. Aside from the ERA-I, the other reanalyses seem to agree with the NOAA STAR anomalies during the El Chichón volcanic period (1982-1984), with the exception of MERRA and MERRA-2, which have

smaller anomalies during the Mt. Pinatubo volcanic period (1991-1993). There is a noticeable decrease in the reanalyses anomalies with respect to the NOAA STAR anomalies in 1999 followed by a gradual increase in time until 2006, after which the reanalyses begin to disagree more with each other. GPSRO observations from the COS-MIC constellation became available for assimilation in 2006.

The SSU1 temperature anomalies from the CFSR/CFSv2 show large temperature jumps associated with the six streams, preventing any useful evaluation. The other four reanalyses differ from the NOAA STAR by less than ±0.5K for most of the time series. The ERA-I, MERRA, MERRA-2, and JRA-55 all show smaller anomalies than the NOAA STAR in the early 1980s. There is minor disagreement among the four reanalyses with the NOAA STAR between the late 1980s and the early 2000s. MERRA exhibits two spikes in the SSU1 and SSU2 differences from NOAA STAR. The first spike is a result of missing SSU data from 8 April - 21 May 1996. The second is from a lack of AMSU-A channel 14 data on NOAA-15 from 30 October-31 December 2000 (W. McCarthy, personal communication, 2017). When there are no observations to constrain the model in the upper stratosphere, analyses migrate to the model climatology, which is warmer than the observations. MERRA-2 found the missing SSU observations in 1996 and began using

Figure 3.21: Time series plots of the global layer mean temperature anomalies (K) from the 1981 - 2010 climatology (*a* - *c*) and reanalyses anomaly differences from the NOAA STAR anomalies (*d* - *f*) for (*a*, *d*) the lower stratosphere (TLS) equivalent to the MSU 4 observations, (*b*, *e*) the middle stratosphere (SSU1) equivalent to the SSU channel 1 observations, and (*c*, *f*) the upper stratosphere (SSU2) equivalent to the SSU channel 2 observations. TLS, SSU1, and SSU2 weights are applied to the MERRA-2, MERRA, ERA-I, JRA-55, and CFSR/CFSv2 pressure-level data to produce layer mean temperatures and anomalies. NOAA STAR TLS, SSU1, and SSU2 anomalies are plotted along with the reanalyses in the left column. Reproduced from Long et al. (2017).

Figure 3.22: Time series plot of the (a) global annual average of the lower stratospheric temperature layer (TLS) temperatures (°C) for MERRA-2, ERA-Interim, JRA-55, CFSR/CFSv2, and the NOAA STAR TLS CDR. (b) The TLS temperature SD (K) of the four reanalyses for each year. The climatological period spanned from 1981–2010. COSMIC GPSRO observations began to be assimilated in 2006. Reproduced from Long et al. (2017).

NOAA-16 AMSU-A observations earlier than in MERRA to shrink the gap to just several days. Beginning in 2006, just as with the TLS anomalies, the disagreement among the four reanalyses increases.

Just as with the SSU1 anomalies, the large temperature jumps associated with the CFSR stream transitions prevent a proper evaluation of its SSU2 time series. Aside from the CFSR, the other four reanalyses are within ± 0.5 K of the NOAA STAR anomalies. The JRA-55 matches the NOAA STAR SSU2 observations very well throughout the entire time series with the exception of a period in the late 1990s and early 2000s when its anomalies are smaller than the NOAA STAR anomalies. The ERA-I matches the NOAA STAR SSU2 observations very well except after 2006 when it exhibits a positive trend. *Simmons et al.* (2014) state that the use of radiosonde data that are not bias adjusted is the likely cause of this trend. MERRA initially begins with lower SSU2 anomalies than NOAA STAR, whereas MERRA-2 anomalies are much closer to the NOAA STAR anomalies. MERRA-2 separates from MERRA after 2005 with more negative anomalies. This is most likely due to the assimilation of MLS temperatures at pressures less than 5 hPa, which have been shown to produce lower temperatures than before 2005.

The CFSR/CFSv2, JRA-55, ERA-I, and MERRA-2 all use GPSRO observations after 2006, yet the later years in **Figure 3.21** show that their anomalies increasingly disagree with each other after 2006. This apparent larger disagreement is because in **Figure 3.21**, the anomalies are calculated from the climatology of each reanalysis and because the climatology differs for different reanalyses quantitatively; thus, **Figure 3.21** may give us wrong impression in terms of the actual differences among the reanalyses. **Figure 3.22a** presents the actual TLS temperatures for these

Figure 3.23: Mean vertical profile temperature differences (solid) and their variability (dashed) of four reanalyses from South Pole ozonesonde temperatures for the months of January (left) and July (right) separated into pre-1998 (top) and post-1999 (bottom) periods. The reanalyses are CFSR/CFSv2, MERRA-2, ERA-I, and JRA55. Note that in July during the pre-1998 period that ERA-I and MERRA-2 have opposite sign differences from the ozonesonde temperatures (see the plus and minus symbols for [ERA-I minus MERRA-2] on the panel). Note also that in the post-1999 period all of the reanalysis mean differences and their variability are much smaller than during the pre-1998 period.

four reanalyses over time from 1980-2014. There is a large spread in the TLS temperatures of 0.8K between the coldest TLS temperature (ERA-I) and the warmest TLS temperature (CFSR/CFSv2). Over time this large spread decreases until the difference is less than 0.1 K. This illustrates how the various reanalyses actually approach agreement of the TLS values as more observations are assimilated. Figure 3.22b presents the SD of the four reanalyses TLS temperatures over time. There is a large decrease from 1986 to 1987, which is attributed to the CFSR/CFSv2 TLS values cooling during the transition from its initial stream to its second. Another drop in 1999 follows the availability of ATOVS in Figure 3.21; the quality and character of the temperature values between 1981 and 2010 changed. This makes generating long-term climatology and anomalies misleading.

Similar comparisons of the SSU1 and SSU2 temperatures are not presented as the temperature biases of each reanalysis above 10 hPa prevents agreement in the layer mean temperature. This shows the value of the GPSRO data to anchor the temperatures in the middle and lower stratosphere, which is where most of the TLS weighting function occurs.

3.7.4 Ringing of SH polar latitude temperature differences

MERRA-2 and ERA-I SH polar temperatures at 50hPa agree well (less than ± 0.25 K) during September in the ATOVS period but have about a 1K difference in the TOVS period. JRA-55 and CFSR/CFSv2 also show this 1 K colder temperature difference from MERRA-2 during the TOVS period. An examination of other months reveals that this difference exists during the SH winter months. Examining the [ERA-I - MERRA-2] differences during the TOVS period at other levels reveals that an oscillating (ringing) set of differences in the SH polar latitudes starts with positive differences at 100hPa; negative differences at 50hPa; positive differences at 10-20hPa; negative differences at 3hPa; and positive differences at 1hPa. This 'ringing' of temperature differences is much smaller during the SH summer months and just partially occurs in the NH polar latitudes with positive differences at 5 hPa and negative differences at 2 hPa.

Figure 3.23 shows the differences of MERRA-2 and ERA-I (as well as JRA-55 and CFSR/CFSv2) from the South Pole ozonesonde temperatures (obtained from the NDACC) in July and January separating the TOVS period (1979 - 1998) and ATOVS period (1999-2014). When one has positive differences from the ozonesonde temperatures the other has negative differences. The maxima of these differences occur from 100hPa-70hPa, at 50hPa, and 20hPa-10hPa. CFSR/CFSv2 and JRA-55 do not show an oscillating pattern in their differences from the ozonesonde temperature, but rather an increasing negative difference with altitude from 100 hPa to 10 hPa. During January all four reanalyses agree well with the South Pole ozonesonde temperatures from 100hPa up to 50 hPa. At higher altitudes, all four show negative differences at 30hPa and 20hPa. During

the ATOVS period, differences from the South Pole ozonesonde temperatures are much smaller (-1 K to 0 K) during July and even smaller (except for ERA-I which shows a consistent cold bias) during January.

The likely candidate for this 'ringing' during the TOVS period is how the reanalyses assimilate the three broader SSU channels vs. the narrower five AMSU channels (10-14) during the ATOVS period and how the assimilation systems handle the propagation of errors in the vertical.

3.8 Comparisons against other observations

3.8.1 Ozonesonde temperatures

Most radiosonde temperature observations are assimilated by the reanalyses. This makes comparisons of reanalyses with radiosondes problematic since the reanalyses should differ least at these observation points. However, temperature profiles accompanying ozonesondes are not assimilated by the reanalyses and thus are a viable source for comparison in the lower and middle stratosphere. Four ozonesonde locations (Ny Ålesund, 79°N, 12°E, beginning 1992; Hohenpeissenberg, 48°N, 11°E, beginning 1987; Lauder, 45°S, 170°E, beginning 1986; and Neumayer, 70°S, 8°W, beginning 1992) obtained from the NDACC were chosen to compare their temperature profiles with that from reanalyses. These locations had the greatest longevity and consistency in ozonesonde measurements. Figure 3.24 shows that there is nearly a 30% reduction of ozonesonde flights from 10 hPa to 7 hPa. An additional 50 % do not reach 5 hPa, and only a few reach 3 hPa. This makes analysis of differences with these radiosonde temperatures above 10hPa impractical. Figure 3.25 presents the annual mean differences and standard deviations of CFSR/CFSv2, MERRA, and ERA-I from the radiosonde observations upward from 100 hPa. Of the four locations, only Lauder shows substantial differences from the observations from 100hPa to 10hPa. The variability of the differences is consistently about 2K

Figure 3.24: Total number of temperature observations made at each pressure level in the lower and mid-stratosphere at Ny Ålesend, Hohenpeissenberg, Lauder, and Neumayer since observations started at each site. Hohenpeissenberg has a higher frequency of ozonesonde launches per month than the other three sites. Note

rapidly above 10 hPa. Ozonesonde data is from the NDACC.

Figure 3.25: Mean (solid line) and standard deviation (dashed line) of temperature differences (°C) of three reanalysis (CFSR/CFSv2, MERRA, and ERA-I) from ozonesonde observed temperatures at a) Ny-Ålesund, b) Hohenpeissenberg, c) Lauder, and d) Neumayer. Ozonesonde data is from the NDACC.

at all altitudes at Ny Ålesund and Hohenpeissenberg. At Neumayer the difference variability is 2 K at 100 hPa, but increases to 4 K at 10 hPa. At Lauder, the variability of differences is nearly 3 K at 100 hPa and grows to nearly 6 K at 10 Pa. The relatively small mean difference and variability of differences of the reanalyses temperatures from observations at Ny Ålesund and Hohenpeissenberg indicate that over the northern hemisphere land masses the reanalyses temperatures are quite good. The large differences from the Lauder observations could be attributed to poorer analyses by the reanalyses since few radiosonde observations are available to be assimilated in the SH middle latitudes. The larger variability of differences at Neumayer indicates increased uncertainty of the reanalyses over Antarctica.

3.8.2 Long-duration balloon observations

Long duration balloons (LDB) are closed, non-expansive, super-pressure, plastic balloons capable of performing 'horizontal' soundings in the atmosphere. They remain on a constant density surface and are advected by the winds. A balloon's 'lifetime' is limited only by leaks of the lifting gas, atmospheric energy, and political or safety considerations. The first LDB were used by the US Navy to collect meteorological data at 300hPa upwind of the continental US over the Pacific Ocean. Each balloon flight lasted several days and they were tracked by radio triangulation (*Angell*, 1960). Other LDB programs include:

• The NCAR "GHOST" program from 1967-71. This consisted of 60 flights at pressure levels between 200hPa and 100hPa. The emphasis was towards monitoring the circulation in the Southern Hemisphere upper troposphere (Angell, 1972).

• The French-US "Eole" Program from August 1971 to December 1972. This program launched 480 balloons taking over 80,000 observations (or more than 600 observations per day) near the 200 hPa pressure level in the SH mid and high latitudes. Satellites were used to obtain several positions per day for each balloon (*Hertzog et al.*, 2006). Along with winds, the balloons provided temperature and pressure observations.

• The Vorcore Campaign from September 2005 to February 2006 over Antarctica. This program included 27 balloons that flew between 60hPa and 80hPa. GPS positioning was used to determine the winds and pressure and temperature observations were communicated with the ground station. Observations were determined at a frequency of (*Beasure et al.* 2009)

15 minutes (Boccara et al., 2008).

 The French Space Agency (Centre National d'Etudes Spatiales (CNES)) Pre-Concordiasi took place in February 2010 and consisted of three flights, lasting about three months. Observations were taken every 30 seconds of winds, pressure and temperature in the equatorial upper troposphere – lower stratosphere (UTLS) or Tropical Tropopause Layer (TTL) (*Podglajen et al.*, 2014).

The Eole, Vorcore, and Pre-Concordiasi observations of temperature and winds have been compared to ERA-40 and *R1*, ECMWF operations and *R1*, and ECMWF operations, ERA-I and MERRA, respectively. None of these balloon observations were assimilated by the reanalyses or ECMWF operations. The Eole observations showed that both ERA-40 and *R1* were warmer than the balloon observations in the subtropics but colder at higher latitudes. Eole observations also showed that the analysis of meteorological wind fields over the open oceans was much better in *R1* than in ERA-40. *Boccara et al.*, 2008 noted that over Antarctica during the 2005 austral spring the "ECMWF analyses were found to

agree closely with the observations with virtually no bias on the zonal and meridional velocities and a small cold bias (-0.42 K) on the temperature. The velocities from the NCEP-NCAR reanalysis [equivalent to *R1*] reanalyses are also very close to the balloon observations although they exhibit larger dispersion. Overall, R-1 displayed a strong warm bias (+1.51 K)". The Pre-Concordiasi observations showed that the scarcity of upper air wind observations by radiosonde or aircraft in the Tropical Tropopause Layer impacted the reanalyses' ability to properly resolve small and mesoscale motions in the wind fields.

3.8.3 Rocketsonde observations

A four decade analysis of radiosondes (1969-present), M-100 rocketsondes (1971 - 1991), RH-200 rocketsondes (2002 - present) and high altitude radiosondes (1969-present) taking measurements on a weekly to two-week frequency has been performed by Das et al. (2016). Observations from all the above were taken at the Thumba Equatorial Rocket Launching Station (TERLS), India (8.5°N, 76.9°E). M-100 rocketsonde observations between 1969-1991 at Volgagrad, Russia (49°N, 44°E), Heiss Island (81°N, 58°E), and Molodezhnava (68°S, 46°E) are also available for analysis. Monthly means were determined between 1970 and 2014. Comparisons were generated between the rocket and radiosonde observations and R2, ERA-40, ERA-I, and MERRA for zonal and meridional wind. Comparisons of winds were generated from the surface up to 30km (~10hPa) from radiosondes and 30km to 65km (~10hPa - 0.1hPa) from rocketsondes. RMS errors of the reanalyses zonal wind was about 2ms⁻¹ below 10km, growing to about 4 m s⁻¹ at 30 km, continuing to increase to 6 m s⁻¹ by 65 km. Meridional winds had an RMS difference of about 2ms⁻¹ up 10km, peaking in the troposphere at 15km at about 2.5 m s⁻¹, declining to 2 m s⁻¹ at 20 km, then slowly increasing to 6 m s⁻¹ at 50 km. Filtering the observed and reanalysis zonal winds into their annual oscillation, SAO, and QBO components show that the annual oscillation, QBO, and SAO are all reproduced by the reanalyses and their structures in the vertical are comparable with the observations at Thumba. However, MERRA's difference with the annual oscillation observations increase from 0ms⁻¹ to 10ms⁻¹ from 50km to 65km, and the SAO winds above 40km are overestimated by MERRA by 5ms⁻¹. The QBO amplitude growth from 20km to 25km is captured by all the reanalyses, but their amplitude with respect to observations is underestimated between 25km to 30km.

3.9 Effects of volcanic eruptions and other natural variabilities

A paper by *Mitchell et al.* (2015) examined nine reanalyses to isolate zonal-mean temperature and zonal wind signatures of variability in the stratosphere and troposphere associated with the two volcanic eruptions (El Chichón, and Mt Pinatubo), El Niño–Southern Oscillation (ENSO), the QBO of the equatorial zonal wind, and the 11-year solar

cycle. Mitchell et al.(2015) also examined in greater detail the seasonal evolution of the 11-year solar cycle signal that operate in the stratosphere and may penetrate downward to influence the troposphere. Employing a multiple linear regression technique with no time lags, Mitchell et al. (2015) found that the characteristic signals of all four sources of variability were very consistent between each of the reanalyses over the 1979 - 2009 period. They found that ENSO imparts a high temperature anomaly in the equatorial troposphere and strengthens the westerly winds in the subtropics. They also found that ENSO has an influence upon the Southern Annular Mode (SAM) with associated zonal wind anomalies in the SH mid-latitude and sub-polar regions. Influences in the stratosphere were also found that imparted a temperature anomaly above the tropical tropopause. This may impact the lower region of the QBO. There is also a warm winter anomaly in the NH polar mid / upper stratosphere that is indicative of increased wave propagation into the winter stratosphere during strong El Niño events. The consensus volcanic response is a warm anomaly in the tropical lower stratosphere, cool anomaly in the upper tropical stratosphere, and wide spread cooling in the troposphere. There is a triple temperature and wind anomaly (positive/negative/positive) response over the equator associated with the QBO. The upper positive response indicates that the QBO has an influence upon the SAO. The 11-year solar cycle response is weaker and less statistically significant than the atmosphere's response to other forcings. A tropical warm anomaly under solar maximum conditions may influence planetary wave propagation toward the poles which is most apparent during the winter months.

Furthermore, Fujiwara et al. (2015) analysed the volcanic temperature responses to the 1982 El Chichón and 1991 Mount Pinatubo eruptions individually using nine reanalysis data sets (JRA-55, MERRA, ERA-I, CFSR/CFSv2, JRA-25, ERA-40, R1, R2, and 20CR). They found that the latitude-pressure distribution of volcanic temperature responses was different for different eruptions, but was quite similar at least among the recent four reanalysis data sets (JRA-55, MERRA, ERA-Interim, and CFSR/CFSv2) for each eruption. The R1, R2, and JRA-25 showed different tropical stratospheric signals particularly for the El Chichón eruption, though the original upper-air temperature observations assimilated are basically common, and this is most probably in association with the use of older analysis systems. The 20CR did not assimilate upper-air observations and gives very different volcanic signals, despite including volcanic aerosols in the forecast model (this is in part due to unknown warming signals in 20CR in 1989 and in 1990 that raised the 36-month averaged base in the volcanic signal definition). They also analysed the response to the 1963 Mount Agung eruption using JRA-55, ERA-40, R1, and 20CR, and concluded that the JRA-55 data set is probably the most ideally suited for studies of the response to the Mount Agung eruption because it is the only data set that employs the most recent reanalysis system.

3.10 Summary and conclusions

In this chapter a comparison of monthly zonal mean temperatures and zonal winds from the five more recent reanalyses and several older reanalyses were evaluated and intercompared. Our initial evaluation was to look for temperature discontinuities in the time series of each of the reanalyses. This showed that the earlier reanalyses (ERA-40 and JRA-25) had multiple temporal discontinuities in the 1980s in the stratosphere associated with changes in the biases of the data from the NOAA TOVS and SSU instruments. The R1 and R2 did not show such discontinuities because they used NESDIS-generated temperature profiles, not the original radiance data. NESDIS most likely strived to minimize such discontinuities in the profile temperatures. Almost all the reanalyses have a temporal discontinuity in 1998 when the ATOVS observations became available and the reanalyses either switched immediately or transitioned from the TOVS to the ATOVS over several years. The CFSR has temporal discontinuities at the time of switching from one stream to the next. The CFSR bias corrected the top SSU channel 3. The model used by the CFSR had a warm bias in the upper stratosphere and slowly warmed about 5K during the course of each stream. Because of the presence of the discontinuities and transitions discussed above, great caution should be exercised in using reanalyses for trend analysis and/ or trend detection, especially in the middle and upper stratosphere.

So as not to favour any one particular reanalysis, a reanalysis ensemble mean (REM) of three of the more recent reanalyses (MERRA, ERA-I, and JRA-55) was generated. We presented the climatological mean (1981-2010) of the temperature and zonal wind REM and showed the altitudes and seasons with the largest variance in the REM. The temperature and zonal winds have the greatest inter-annual variability in the NH polar region from January through March because of the large variability in wave activity, including the frequent occurrence of strong stratospheric warming events. This variability is greatest in the upper stratosphere as planetary-scale wave amplitudes and the associated temperature and zonal wind changes during strong stratospheric warming events are largest in the upper stratosphere. In the SH polar region, the inter-annual variability is not as large in magnitude and is prevalent throughout the stratosphere. Because midwinter wave activity is much smaller in the SH, most of the inter-annual variability in the SH polar region is associated with the springtime transition to summer circulation patterns and polar vortex breakdown when wave activity shows larger inter-annual variability in timing and magnitude.

Time series of the temperature variance in the three REM members showed that the greatest disagreement occurs during the TOVS time period (1979–1998) in all latitude zones, and agreement improves during the ATOVS time period (1999 to present). The disagreement in the SH polar latitudes extended lower into the stratosphere than in the NH polar latitudes. The zonal wind variance was smaller than the temperature variance in the polar latitudes, but had a similar temporal

difference between the TOVS and ATOVS time periods. In the tropics, the zonal wind variance was much larger than in the polar regions as the disagreement of the SAO and QBO zonal winds was quite large. Thus, improving equatorial winds in future reanalyses is an important goal.

The characteristics of each reanalysis were identified as differences from the temperature and zonal wind REM. The CFSR/ CFSv2 had a seasonal warm bias compared to the REM in the upper stratosphere that persisted during both the TOVS and ATOVS time periods. The JRA-55, on the other hand, had a seasonal cold bias that persisted during both the TOVS and ATOVS time periods. ERA-I and MERRA had smaller differences from the temperature REM except that the ERA-I had a warm bias in the SH polar latitudes between 7hPa and 5hPa that occurred only during the austral winter and only during the TOVS time period. MERRA-2 had very small differences from the REM except in the upper stratosphere in the polar regions where it had a year-long cool bias at 1 hPa and a warm bias between 2hPa and 3hPa. These biases greatly diminished during the ATOVS period. Temperature differences from the REM in the earlier reanalyses (JRA-25, ERA-40, and R1) extended throughout the stratosphere and the upper troposphere. These differences occurred through both the TOVS and ATOVS time periods. This illustrates the progress made by the reanalysis centres to improve the analyses from the earlier versions to the later versions. This results in better agreement among the more recent reanalyses.

In the tropics, the individual reanalyses exhibited smaller temperature differences than in the polar latitudes. However, the characteristic biases in the upper stratosphere observed in the polar latitudes were maintained in the tropics. The zonal wind differences from the REM of the individual reanalyses are very large in the SAO region. In the QBO region the differences frequently show dissimilarities in the timing of the descending westerlies and easterlies as well as the amplitude of these winds. Zonal wind differences from the REM were not confined to the stratosphere as several reanalyses also had sizable differences in the troposphere.

Specifically comparing the more recent reanalyses QBO zonal winds (70hPa-10hPa) against the zonal winds observed at Singapore using the FUB data set showed that the CFSR/CFSv2 had the largest RMS differences from the Singapore winds than the other reanalyses at most levels and during both the TOVS and ATOVS periods However, MERRA-2 10 hPa zonal winds were nearly twice as large as the other reanalyses during the TOVS period, mostly due to an overly aggressive gravity wave parametrisation. The RMS differences from the Singapore zonal winds were smaller during the ATOVS period for all the reanalyses. The CFSR/CFSv2 had the largest amplitude biases from the Singapore winds as shown by the linear slope of their matched monthly values. The linear slopes of all the reanalyses were furthest from unity at 50hPa and 30 hPa during the TOVS period.

There are several reasons why the ATOVS period is an improvement over the TOVS period. The primary reason is that the AMSU-A instrument has five narrower channels in the stratosphere instead of the broader three SSU channels. (The MSU channel 4 and AMSU-A channel 9 weighting functions are almost identical.) Another reason is that the SSU was the only instrument monitoring the thermal structure of the stratosphere from 1978 through 1998. From 1999 onward, there are additional satellite instruments monitoring the stratosphere: AIRS, IASI, MLS, and GPSRO. Hence the quantity and quality of data monitoring in the stratosphere increases from 1999 to the present.

The amplitude of the annual temperature cycle (warmest summer month minus the coldest winter month) in the SH polar latitudes is larger than the NH polar latitude temperature amplitude by 5-15 K. The region of large amplitude extends throughout the middle and upper stratosphere in the SH polar latitudes. In the NH polar latitudes, the vertical region of large temperature amplitudes is confined to the upper stratosphere and occurs during the years with an SSW. The ERA-I has a noticeably smaller annual temperature amplitude in the SH polar latitudes than the other ensemble members from 3hPa to 30hPa. This is due to its warm bias during the SH winter months in this latitude region. The CFSR/CFSv2 temperature amplitude decreases rapidly above 3hPa due to its warm bias in the upper stratosphere in both SH and NH polar latitudes.

Comparisons against HIRDLS (January 2005 - March 2008) and Aura MLS (2005 - 2014) temperatures concur with the previous characteristics of the various reanalyses in the upper stratosphere. The CFSR has a definite warm bias compared to HIRDLS temperatures, while the JRA-55 has a definite cold bias. Both MER-RA and ERA-I have a slight warm bias during the summer months between 3hPa and 7 hPa. MERRA has a slight cold bias above this between 1 and 2 hPa nearly all year long. MER-RA-2 assimilates Aura MLS temperatures at pressures less than 5 hPa and consequently differences are very small.

The NOAA STAR TLS, SSU1, and SSU2 data sets (Zou and Qian, 2016; Zou et al., 2014) are a much-improved CDR than the version used in Thompson et al. (2012), which pointed out the dissimilarities between the NOAA and Met Office SSU data records. The comparison between the version used in this chapter and the appropriately weighted reanalyses is much better than previous papers using the older version and the Met Office CDR. All of the more recent reanalyses capture the characteristics of the NOAA STAR TLS anomalies. Excluding the CFSR/CFSv2, the other reanalyses (MERRA-2, MERRA, ERA-I, and JRA-55) capture the basic features of the SSU1 and SSU anomalies. We learn from this intercomparison that the GPSRO observations provide an anchor that drives the reanalyses to closer agreement in the middle and lower stratosphere. We also learn that using a long period climatology may not be the best practice to generate anomalies in parts of the atmosphere which are more sensitive to the changes in data sources, which impacts their quality and accuracy over time.

Temperature soundings at four ozonesonde locations extending back to the late 1980's and early 1990's were used to compare against CFSR/CFSv2, MERRA, and ERA-I. The long-term mean differences show that the reanalyses do well below 10hPa in the NH high (Ny Ålesend) and mid latitudes (Hohenpeissenberg). Similar mean temperature differences were observed over Antarctica (Neumayer) but with increasing standard deviation with height. Larger mean differences and standard

Figure 3.26: Evaluation of specified diagnostics for each reanalysis. Four evaluation characterizations are provided: "Demonstrated Suitable" (dark green), "Suitable with Limitations" (light green), "Use with Caution" (yellow), and "Demonstrated Unsuitable" (red). Note that the score corresponding to "demonstrated suitable" was not assigned to any of the diagnostics listed here, so the darkest green colour does not appear in this table. Diagnostics relate to: Use of temperatures above/below 10 hPa and before/after 1998; QBO zonal winds and polar zonal winds before/after 1998; and temperature layer differences from the Climate Data Record (CDR) for MSU channel 4, and SSU Channels 1, 2, and 3. Note that the score coresponding to "Demonstrated Suitable" (dark green) was not assigned to any reanalysis for any diagnostic.

deviations with height were observed over Lauder.

Additional studies extending over several decades have examined other aspects of the dynamical features of reanalyses in the upper troposphere and stratosphere. These studies have used long duration balloons at multiple geographic regions of the globe (*Podglajen et al.*, 2014; *Baccara et al.*, 2008; *Hertzog et al.*, 2006) and historical radiosonde and rocketsonde flight information over India and Russia (*Das et al.*, 2016). Using linear regression techniques, *Mitchell et al.*, (2015) examined reanalyses for impacts on both hemisphere's annular modes and wave activity from multiple sources of variability (ENSO, QBO, volcanoes, and the solar cycle). *Fujiwara et al.* (2015) used multiple reanalyses to examine their temperature response to the El Chichón and Mt. Pinatubo volcanic eruptions.

3.11 Key findings and recommendations

In this chapter we have examined the thermal and dynamical characteristics of the older and the more recent reanalyses. A summary of the diagnostics evaluated in this chapter is provided in **Figure 3.26**. This figure contains assessments of the reanalysis representation of key diagnostics related to temperature and winds and directs the reader towards the appropriate chapter section for further information.

Key Findings:

- More recent reanalysis from all centres are better than their previous version (e.g., JRA-55 vs. JRA-25; MERRA-2 vs. MERRA).
- Due to changes in available data sources, drifts and jumps in the long-term temperature time series can occur. These irregularities are greatest above 10hPa. Greatest caution is advised when determining trends with reanalysis temperature data sets above 10hPa.
- The more recent reanalyses have fewer discontinuities in their temperature and wind time series due to better data assimilation techniques and transition among different sets of observations.
- The transition from the TOVS to ATOVS satellite periods, starting around 1998-1999, is problematic for all reanalyses. In the stratosphere, the transision from three broad SSU IR channels to 5 narrower AMSU/ATMS microwave layers proves to be problematic for data assimilation.
- The more recent reanalyses agree quite well with each other in the lower and middle stratosphere. All reanalyses have greater differences in the upper stratosphere and lower mesosphere. The latter discrepancies result from differences in model top, vertical resolution, data assimilation techniques and data that is assimilated. *Chapter 2* provides detailed information about each reanalyis model's structure and physics.
- Temperature biases exist among the various reanalyses in the UTLS especially before 1998. Temperatures do not harmonize until GNSS-RO observations are used to lock in the temperatures after 2005.
- The reanalysis QBO winds show improvement over time. Separating them into the TOVS and ATOVS periods, the ATOVS period agree much better with the Singapore radiosonde observations than during the TOVS period. We expect that future reanalyses will have QBO winds that agree with observations as their forecast models improve to produce a spontaneous QBO in the tropics.

Recommendations:

- Users of any reanalysis should proceed with greatest caution when intercomparing reanalyses, and particularly when attempting to detect trends and/or changes in climate above the tropopause.
- Improving the TOVS time period would be highly beneficial to future reanalyses. However, the TOVS time period may never be as good as the ATOVS period due to the sparsity of data.
- Model improvements, improvements to the variational bias corrections to handle the broad SSU weighting functions, and non-orographic gravity wave parametrisation improvements (so the forecast models can generate a QBO on their own) are some of the ways the TOVS time period can be improved upon.
- It may benefit each 'satellite era' reanalysis to begin their reanalysis several years earlier using just conventional data. This most likely will help harmonize the reanalyses' temperature structure below 10 hPa at the start of assimilating satellite data.

Major abbreviations and terms

20CR	20th Century Reanalysis of NOAA and CIRES
AIRS	AIRS : Atmospheric InfraRed Sounder
AMSU	Advanced Microwave Sounding Unit (AMSU-A for Unit A)
ATOVS	Advanced TIROS Operational Vertical Sounder
Aura	A satellite in the EOS A-Train satellite constellation
CDAS-T574	Climate Data Assimillation System T574 resolution
CDR	Climate Data Record
CFSR	Climate Forecast System Reanalysis of NCEP
CIRA86	COSPAR International Reference Atmosphere, 1986
CIRES	Cooperative Institute for Research in Environmental Sciences (NOAA and the University of Colorado Boulder)
CFSR	Climate Forecast System Reanalysis of NCEP
CFSv2	CFSv2 : Climate Forecast System version 2. Post 2010 version of CFSR
CNES	Centre national d'études spatiales
COSMIC	Constellation Observing System for Meteorology, Ionosphere, and Climate
COSPAR	Committee on Space Research
CRTM	Community Radiative Transfer Model
DOE	Department of Energy
ECMWF	European Centre for Medium-Range Weather Forecasts
ENSO	El Niño Southern Oscillation
EOS	NASA Earth Observing System
ERA5	ECMWF Reanalysis version 5
ERA-15	ECMWF 15-year reanalysis
ERA-40	ECMWF 40-year reanalysis
ERA-I or ERA-Interim	ECMWF interim reanalysis
GENESIS	Global Environmental and Earth Science Information System
GHOST	Global Horizontal Sounding Technique
GLATOVS	Goddard Laboratory for Atmospheres TOVS forward model
GMAO	Goddard Modeling and Assimilation Office
GPSRO	Global Positioning System radio occultation
GSI	Gridpoint Statistical Interpolation
HIRDLS	High Resolution Dynamics Limb Sounder
IASI	Infrared Atmospheric Sounding Interferometer
ITCZ	InterTropical Convergence Zone
JMA	Japanese Meteorological Agency
JRA-25	Japanese 25-year reanalysis
JRA-55	Japanese 55-year reanalysis
JPL	Jet Propulsion Laboratory
LDB	Long Duration Balloon
MERRA	Modern Era Retrospective-Analysis for Research (MERRA-2 for its version2)
MLS	Microwave Limb Sounder

MSU	Microwave Sounding Unit
NASA	National Aeronautics and Space Administration
NCAR	National Center for Atmospheric Research
NCEP	National Centers for Environmental Prediction of NOAA
NDACC	Network for the Detection of Atmospheric Composition Change
NESDIS	National Environmental Satellite, Data, and Information Service of NOAA
NH	Northern Hemisphere
NOAA	National Oceanic and Atmospheric Administration
NOAA-*	NOAA polar-orbiting operational meteorological satellite (* indicates the satellite number)
QBO	Quasi-biennial oscillation
R1	NCEP-NCAR Reanalysis 1
R2	NCEP-DOE Reanalysis 2
REM	Reanalysis ensemble mean
RMS	Root mean square
RTM	Radiative Transfer Model
S-RIP	SPARC Reanalysis Intercomparison Project
SAM	Southern Annular Mode
SAO	Semi-annual oscillation
SD	Standard Deviation
SH	Southern Hemisphere
SPARC	Stratosphere-troposphere Processes and their Role in Climate
SSU	Stratospheric Sounding Unit (SSU1 and SSU2 for SSU channel 1 and 2, respectively)
SSW	Sudden stratospheric warming
STAR	Center for Satellite Applications and Research of NESDIS
TERLS	Thumba Equatorial Rock Launching Station
TIROS	Television Infrared Observation Satellite
TLS	Temperature of the lower stratosphere (MSU channel 4 and AMSU channel 9)
TOVS	TIROS Operational Vertical Sounder
TTL	Tropical Tropopause Layer
UTLS	Upper Troposphere and Lower Stratosphere
WMO	World Meteorological Organization
